CHAPTER 119

Lymphoproliferative Diseases Involving the Lung

Venerino Poletti
Sara Piciucchi
Silvia Asioli

INTRODUCTION

Nomenclature and classification schemes of lymphoproliferative disorders have undergone changes over the past 20 years. Malignant lesions are now best classified according to the current World Health Organization (WHO) schemes.[1,2] In the lung and pleura, primary lymphoproliferative disorders represent a wide and overlapping spectrum of conditions from reactive polymorphous and polyclonal processes to various entities of malignant lymphomas. The natural history of these diverse conditions is variable, and further heterogeneity is recognized within distinct disease entities. Primary pleuropulmonary lymphoproliferative diseases are rare, whereas lymphomas secondarily affecting the lungs occur in up to 20% of autopsy cases. Although most diagnoses are based on light microscopy, immunohistochemical and molecular investigations have assumed a vital role. A schematic classification of lymphoid disorders involving primarily the lung and pleura is shown in Table 119-1.

ANATOMY AND HISTOLOGY OF THE PULMONARY LYMPHOID SYSTEM

Pulmonary lymphatics originate in superficial and deep plexuses; the interalveolar septa and the alveolar ducts and sacs have no lymph vessels.[3] The superficial plexus lies deep to the visceral pleura and in the fibrocollagenous interlobular septa, and its efferents pass around the margins of the lung and its fissures, eventually reaching the bronchopulmonary (hilar) nodes. The deep lymphatics originate at the bronchiolar level and follow the divisions of the bronchial tree and pulmonary vessels up to the lung hilum, ending in the same nodes as the superficial plexus. The lymphatics communicate at lobar, lobular, and pleural boundaries and, thus, serve each other as potential collaterals. These channels ultimately flow into the intrathoracic lymphatic duct, which then typically empties into the left subclavian vein.[4,5] Lymphatics are not usually obvious in histologic sections of normal lung, but they are prominent and open in some of the disorders that manifest with specific lymphatic involvement, such as cardiogenic edema and lymphangitic carcinomatosis. In the latter, lymphatic channels distended with malignant cells are apparent within the visceral pleura, interlobular septa, and adventitia of arteries, veins, and bronchioles. All lymphatics contain valves and extremely thin, flat endothelial cells lining a rudimentary basement membrane. These endothelial cells express characteristic markers, such as podoplanin (a mucin-type transmembrane glycoprotein), lymphatic vessel endothelial hyaluronan receptor 1 (LYVE-1, a CD 44 homolog), products of the homeobox gene PROX1, vascular endothelial growth factor receptor 3 (VEGFR-3), and fibrillin 1 and 2. Larger lymphatics contain smooth muscle cells and collagen.[6]

Small submucosal aggregates of lymphoid cells are often prominent at bronchial bifurcations and near distal respiratory bronchioles (pulmonary microtonsils) and represent bronchus-associated lymphoid tissue (BALT)[7] (Fig. 119-1). Whether humans are born with this specialized secondary lymphoid system, or whether the aggregates of B lymphocytes, T lymphocytes, HLA-DR+ interdigitating cells, follicular dendritic cells, and lymphoid follicles with overlying flattened and attenuated specialized epithelium develop in response to antigenic stimulation is still controversial.[7–11] Viruses, connective tissue disorders, tobacco use, bronchiectasis, and obstructive pneumonia are just a few of the pathologic processes known to induce BALT. Unlike typical lymph nodes that rely on afferent lymphatics for antigen retrieval, BALT is integrated into lung tissue, and antigen is sampled directly from the bronchial and bronchiolar lumens through specialized "lymphoepithelium." This specialized pseudostratified bronchial epithelium is depleted in cilia and goblet cells and infiltrated by T lymphocytes, and it is capable of specific phago-pinocytosis and antigen presentation. Immunoglobulins, most notably IgA, are synthesized and secreted by lymphocytes directly into airway lumens. Amazingly, this system appears capable of mounting a competent adaptive immune response. In addition, BALT B lymphocytes circulate and "home" to other mucosal sites, such as the conjunctiva, salivary glands, stomach, and intestines, to

TABLE 119-1 Classification of Lymphoid Disorders Affecting Only or Mainly Lung and Pleura

Benign Hyperplastic Disorders
Reactive pulmonary lymphoid hyperplasia (nodular)
Follicular bronchitis/bronchiolitis (FBB)
Lymphocytic interstitial pneumonia (LIP)/pulmonary diffuse lymphoid hyperplasia
Common variable immunodeficiency (granulomatous and lymphocytic interstitial pneumonia [GLILD])
Autoimmune lymphoproliferative syndrome
Atypical Lymphoid Hyperplasia
Castleman disease (unicentric, multicentric)
IgG4-related disease
Primary Pulmonary Lymphoid Neoplasms
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Follicular lymphoma
Diffuse large B-cell lymphomas (DLBCL) as a group
(Variants: lymphomatoid granulomatosis, intravascular lymphoma, primary effusion lymphoma, DLBCL associated with chronic Inflammation)
Plasmacytoma
Amyloidosis
Light chain disease
Extranodal natural killer–T cell lymphoma (nasal type)
Peripheral T-cell lymphoma not otherwise specified
Anaplastic large cell lymphoma
Classic Hodgkin lymphoma
Posttransplant Lymphoproliferative Disorders (PTLDs)
PTLD—early (plasmacytic hyperplasia, infectious mononucleosis–like)
PTLD—polymorphic PTLD—monomorphic (classify according to lymphoma classification)

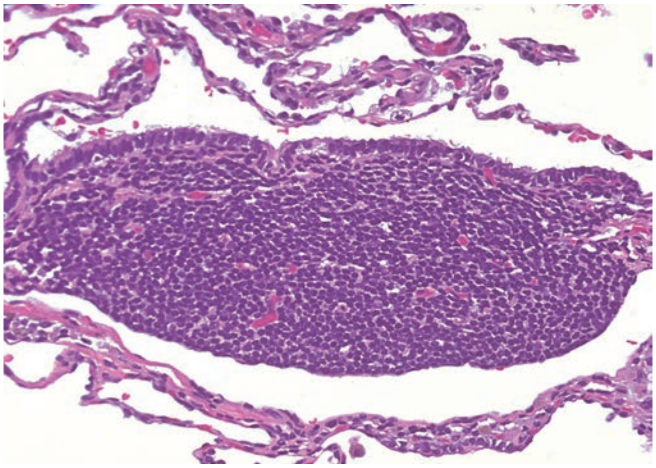

Figure 119-1 Bronchus-associated lymphoid tissue. The submucosal collection of lymphoid cells is intimately associated with overlying bronchiolar epithelium. Hematoxylin and eosin, 40× original magnification.

create a common mucosal immune system—the mucosa-associated lymphoid system (MALT).[12] Thus, responses induced in one location can be replicated at other sites.

Intrapulmonary lymph nodes (IPLs) may be part of the pulmonary immune system and may also be induced by antigenic stimuli, rather than through normal embryologic development.[13] Autopsy studies suggest a prevalence of 18%, and although many are related to bronchi of the first few orders, peripheral subpleural locations are not uncommon. In this age of high-resolution computed tomography (HRCT) and lung cancer screening programs, up to 80% of reported cases of IPLs occur in men with histories of tobacco use, and almost 35% of cases are multiple.[12] They appear as round or angulated, sharply circumscribed subpleural opacities up to 2 cm in diameter and are found along interlobular septa or within major and minor fissures. IPLs histologically resemble classic lymph nodes with well-developed cortical and medullary areas.[13,14] Sinus histiocytes frequently contain abundant anthracosilicotic pigment, and silicotic nodules with calcifications may form. In patients with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), IPLs may be involved and, rarely, primary lung carcinoma or carcinoma from a nonpulmonary site can metastasize to IPLs.

GENERAL CONSIDERATIONS

Although pulmonologists often diagnose pulmonary diseases on the basis of clinical and radiographic findings and rely on tissue samples merely for confirmation, definitive diagnosis of lymphoid lesions of the lung almost invariably is based on histology. Yet clinical and radiologic features often provide essential clues that narrow the differential. For example, a history of Sjögren syndrome and/or the presence of cysts on HRCT should raise suspicion for the presence of lymphoid interstitial pneumonia (LIP).

Bronchoalveolar lavage fluid analysis by flow cytometry or molecular biology techniques may be diagnostic in cases of B-cell lymphomas (mainly MALT lymphoma), especially when the process presents with alveolar consolidations. Endobronchial ultrasound (EBUS)-directed fine-needle aspirates/biopsies of intrathoracic lymph nodes,[15] large core transthoracic biopsies, and transbronchial biopsies supplemented with ancillary studies may suffice for a diagnosis of malignant lymphoma. Transbronchial cryobiopsy may represent a valid diagnostic approach because samples so obtained are significantly large and without crush artifacts. Peripheral structures of the secondary pulmonary lobules may be captured by this approach, and a "lymphangitic distribution" of the lesions may be proven. Furthermore, cryobiopsy provides ample material for immunohistochemistry and molecular biology analyses.[16] However, surgical wedge biopsies may be required for a precise and definite diagnosis, mainly in primary pulmonary Hodgkin lymphoma (HL) and T-cell lymphoma or when the process manifests with scattered nodules in the lungs. Pleuroscopy or video-assisted thoracoscopic surgery (VATS) are the first-choice techniques in cases of pleural effusion when cytologic analysis of the fluid (using morphology, flow cytometry, and molecular biology investigations) obtained by thoracentesis fails.

In addition to histologic examination, immunophenotyping is routinely performed and has become indispensable in diagnosing and classifying lymphoid lesions of the lung.[1,2] Immunohistochemical studies, fluorescence in situ hybridization (FISH), or other molecular biology techniques can be reliably performed on formalin-fixed, paraffin-embedded tissue, whereas flow cytometry is useful for demonstrating immunoglobulin light-chain restriction in fresh tissue. Aberrant antigen expression by either method also allows for subclassification. Polymerase chain reaction (PCR) may be required in up to 20% of cases to prove clonality.[1,2] Either rearrangement of the immunoglobulin heavy-chain gene joining region (*JH*) or the T-cell receptor γ-chain gene (TCR-γ) can be investigated. Lastly, chromosomal abnormalities indicative of specific lymphomas, such as t(14;18) translocation in follicular lymphoma or t(11;14) translocation in mantle cell lymphoma, may be helpful. Because of the strict links between some kinds of malignant lymphoma and viral infections (Epstein-Barr virus [EBV], human herpesvirus 8 [HHV-8], Human Immunodeficiency Virus [HIV], Hepatitis C Virus [HCV], Human T-Lymphotrophic Virus type 1 [HTLV-1]), specific testing for these agents in biopsy samples is part of the diagnostic workup. Lastly, although clonality indicates malignancy, clonality in pulmonary lymphoid lesions may not predict clinical outcome.[17,18]

REACTIVE LYMPHOID PROCESSES

Although the terminology used to describe inflammatory processes of the lung has remained relatively static over the past 25 years, immunohistochemistry and molecular genetic analysis have redefined diagnostic criteria. Processes arising from BALT include nodular lymphoid hyperplasia (NLH), follicular bronchitis/bronchiolitis (FBB), diffuse lymphoid hyperplasia (DLH), and LIP. Common variable immunodeficiency (CVID) and other genetic disorders also may manifest as lymphoid lesions in the lungs.

■ Nodular Lymphoid Hyperplasia

Known to previous generations of pulmonologists and hematopathologists as "pseudolymphoma," this reactive process was recognized as a form of BALT hyperplasia in the mid-1980s. Although NLH was once considered to be quite common, ancillary studies have convincingly demonstrated that most cases were actually low-grade lymphomas. Thus, true NLH is now considered a legitimate, but exceedingly rare, polymorphous nodular lymphoid lesion of the lung. Interestingly, immunohistochemical studies have documented B-cell lymphomas within pre-existing reactive masses of BALT, such that one could, in the most general sense, consider NLH a precursor lesion.

Most affected individuals are middle aged with a nearly equal gender incidence. Patients are usually asymptomatic, although a small percentage may have autoimmune diseases such as systemic lupus erythematosus or Sjögren syndrome, or polyclonal hypergammaglobulinemia. Lesions usually appear as solitary subpleural radiographic nodules with air bronchograms, but several nodules or localized infiltrates can be seen, the latter finding serving as a reminder that the distinction between nodular and diffuse processes is arbitrary. Up to one-third of cases feature regional lymphadenopathy. Excised tan-white rubbery to firm nodules measure from 0.6 to 6.0 cm. Histologically, the well-demarcated lesions may

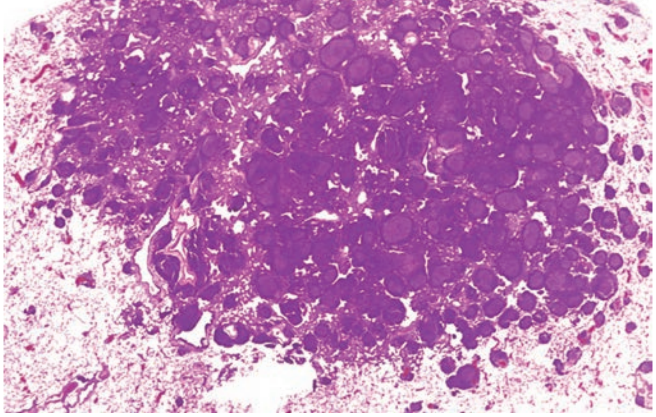

Figure 119-2 Nodular lymphoid hyperplasia. The lesion is composed of benign reactive germinal centers. Although radiographically nodular, germinal centers spill out into surrounding lung. Immunohistochemistry is required to exclude a diagnosis of malignant lymphoma. Hematoxylin and eosin, 1× original magnification.

feature slight extension along alveolar septa and central scarring. Normal lung parenchyma is overrun by large reactive germinal centers with well-preserved mantle zones. Interfollicular areas are filled with plasma cells and mature lymphocytes (Fig. 119-2). The follicles are clearly reactive with a variety of cell types, mitoses, and macrophages. Regional lymph nodes often feature reactive follicular hyperplasia. Histologic diagnosis may be supported by findings observed even in small samples (e.g., regular transbronchial biopsy, transbronchial cryobiopsy, percutaneous guided biopsy).

Immunohistochemical studies demonstrate a mixture of B and T cells. The B cells express both κ and λ light chains without light chain restriction. Aberrant B-cell staining for CD5, CD23, or CD43 is not seen, and the germinal centers do not stain with bcl-2. Immunoglobulin heavy chain gene rearrangement or evidence of t(14;18) breakpoints is not observed. These ancillary findings are of the utmost importance since light microscopy alone may not differentiate NLH from an extranodal marginal zone B-cell lymphoma of MALT. The latter usually features infiltrative growth but may have reactive follicles and polytypic plasma cells with only a focal monotypic cell population. Bronchoalveolar lavage may document an increase of lymphocytes (mainly CD3+ T lymphocytes, but also CD19/CD20+ B lymphocytes without monotypic light chains restriction as assessed in flow cytometry). Positron emission tomography (PET) shows a very low metabolic activity, and surgical excision is done in a significant minority of cases when the suspicion of malignancy is high.

■ Follicular Bronchiolitis

Diffuse lymphocytic lung hyperplasia restricted to the walls of airways and peribronchial tissue is referred to as follicular bronchiolitis (FB).[19–21] FB is often seen in individuals with bronchiectasis, chronic infections, and chronic obstructive pulmonary diseases, including asthma. The entity may also be seen in association with connective tissue diseases, congenital or acquired immunodeficiencies, or bone marrow transplantation, or as a manifestation of a hypersensitivity reaction. FB may also be seen in some occupational exposure settings, for example, nylon flocking workers.[22] Idiopathic forms have been reported.

Patients with FB in association with connective tissue disease are usually in their forties and most often suffer from Sjögren syndrome or rheumatoid arthritis (RA). Rarely it is associated with primary biliary cirrhosis or with chronic hepatitis C virus infection. Patients may also suffer with chronic low-grade infections, such as mycoplasma, chlamydia, adenovirus, or EBV.

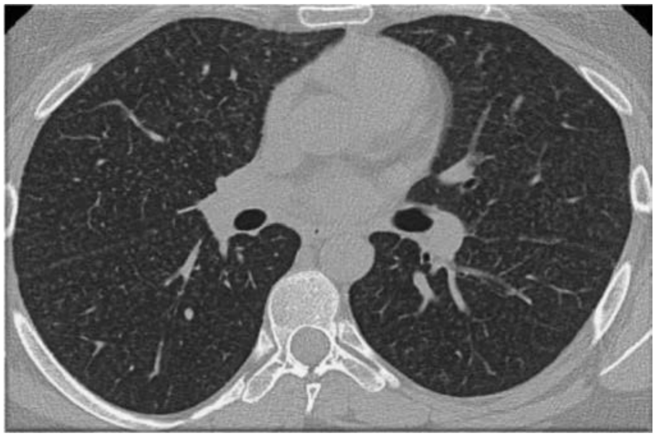

Figure 119-3 CT scan from a patient with Sjögren syndrome demonstrating centrilobular nodules consistent with follicular bronchiolitis.

Individuals with FB present with dyspnea and cough; some may have fever, recurrent pneumonia, or weight loss. Pulmonary function tests reveal restrictive, obstructive, or normal patterns, sometimes with reduced diffusing capacity ($D_{L_{CO}}$). Those with RA often have a very high rheumatoid factor. Peripheral eosinophilia may be noted in those with hypersensitivity syndromes. Chest radiographs feature bilateral diffuse reticular and nodular opacities, whereas HRCT shows up to 12-mm centrilobular and peribronchial nodules, with or without areas of ground-glass opacities[23] (Fig. 119-3). Air trapping also may be a prominent feature. Rarely, cysts as the main feature have been described.[24] Microscopically, nodular aggregates of B cell–rich lymphocytes and plasma cells with reactive germinal centers expand the bronchial and/or bronchiolar submucosa and bulge into, and permeate, overlying epithelium (Fig. 119-4). Rare

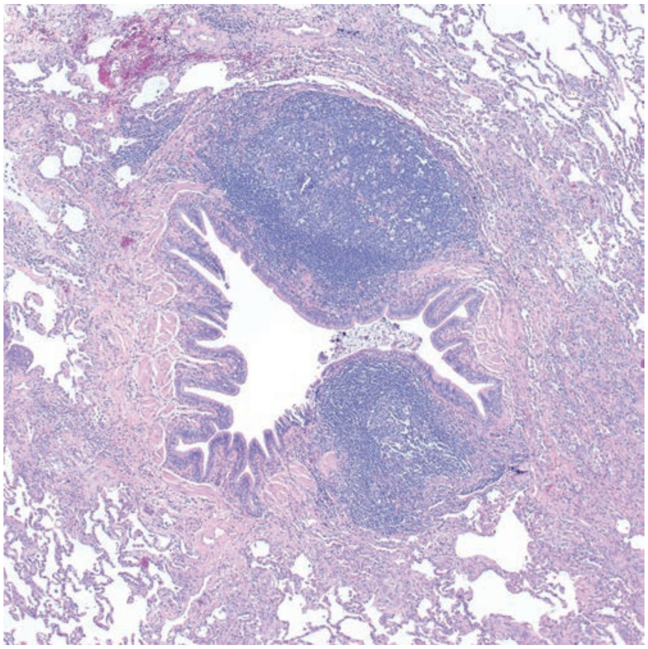

Figure 119-4 Follicular bronchitis/bronchiolitis. Reactive germinal centers expand airway submucosa and compress the lumen. Mucus accumulation often leads to infection and bronchiolectasis. Alveolar parenchyma is spared. Hematoxylin and eosin, 4× original magnification.

T cells wander beyond the follicles into adjacent alveolar septa.[21] Smaller airway lumens are distorted and narrowed, predisposing to mucostasis and subsequent infections. Lymphoid follicles along interlobular septa and beneath the pleura represent a more diffuse form of lymphoid hyperplasia and warrant the descriptive diagnosis of DLH. Bronchoalveolar lavage (BAL) may document an increase of CD3+ lymphocytes and, to a lesser degree, polyclonal B lymphocytes. Lung biopsy (cryobiopsy, VATS) offers definitive diagnosis.[25]

Treatment of FBB with corticosteroids has variable results. Those with peripheral eosinophilia are reportedly steroid-responsive. A prolonged course of low-dose macrolides (after having excluded a mycobacterial infection) may be beneficial.[26]

■ Lymphocytic Interstitial Pneumonia (Diffuse Lymphoid Hyperplasia)

Although LIP is included in the American Thoracic Society/European Respiratory Society (ATS/ERS) classification of idiopathic interstitial pneumonias, this multifactorial, but rarely idiopathic, process represents the most florid form of BALT hyperplasia and may be difficult to differentiate from florid FB and low-grade malignant lymphoma. The morphologic distinction between LIP and diffuse lymphoid hyperplasia is arbitrary.[27] Almost all patients with LIP have immunologic disorders (Sjögren syndrome, systemic lupus erythematosus, RA, Hashimoto thyroiditis, myasthenia gravis, hemolytic anemia, pernicious anemia, chronic active hepatitis, primary biliary cirrhosis), dysproteinemias, or viral infections including EBV and, especially in children, human immunodeficiency virus (HIV).[28,29] LIP may also represent a pulmonary manifestation of chronic graft-versus-host (GVHD) disease in hematopoietic stem cell transplant recipients, or it may be a manifestation of drug-induced lung injury.[30,31]

The clinical presentation includes cough and/or dyspnea in addition to symptoms and signs related to underlying diseases. More than 60% of patients have dysproteinemias, which may precede the onset of LIP or occur any time during the clinical course.[32,33] Most of these cases are associated with hypergammaglobulinemia; only 10% of cases are associated with hypogammaglobulinemia. A monoclonal spike seen with serum immunoelectrophoresis suggests a diagnosis of lymphoma rather than LIP. Pulmonary function tests reveal reduced lung volumes and $\mathrm{DL_{CO}}$, and hypoxia is common. Bronchoalveolar lavage (BAL) analysis shows an increased percentage of lymphocytes, mainly CD3+, but also an increase of polyclonal B cells.

The lungs are typically firm and tan-gray, and end-stage cases feature honeycomb change with subpleural cysts. Although the radiographs and gross appearance suggest parenchymal consolidation, histologically LIP shows a diffuse prominently interstitial infiltrate of small lymphocytes, plasma cells, larger mononuclear cells, and histiocytes (Fig. 119-5). Although the infiltrates are centered on airways, vessels, and interlobular septa, and include peribronchiolar lymphoid follicles, infiltration into alveolar septa is always present and distinguishes LIP from FB. Small nonnecrotizing granulomas, reactive germinal centers, and infiltration into overlying respiratory epithelium are often seen, whereas lymphocytes frequently spill into alveolar spaces. In long-standing lesions, honeycomb changes may be superimposed. HIV-infected patients may show few plasma cells, while occasional cases of LIP are so rich in plasma cells that they have been termed "lymphoplasmacytic pneumonia" or "plasma cell interstitial pneumonia." The lymphoid follicles largely consist of cytologically bland B cells, whereas the interstitial lymphocytes are mostly T cells. Immunoglobulin heavy chain restriction or gene rearrangement is lacking. In addition to malignant lymphoma, nonspecific interstitial pneumonia (NSIP) (the boundaries between these two entities are not always clear), hypersensitivity pneumonitis, and infections, including pneumocystis, should be excluded.

CT demonstrates <3.0-cm thin-walled cysts (Fig. 119-6). They are usually limited in number. Tiny and numerous cysts with a peribronchovascular distribution have been described. Other findings reported are small, ill-defined centrilobular nodules, ground-glass opacities, bronchovascular and interlobular thickening, mosaic attenuation, and enlarged hilar lymph nodes.[34] Cysts may be the only CT scan finding and may be confused with lymphangioleiomyomatosis (LAM) or other cystic lung disorders.[35] The presence of larger calcified nodules suggests the coexistence of nodular amyloidosis.

Given the rarity of LIP, controlled treatment trials have not been undertaken. Corticosteroids are the primary therapy, in addition to other immunosuppressive agents, such as cyclophosphamide and chlorambucil and azathioprine; results are variable. One-third of patients have resolution, one-third stabilize, and the remaining third progress. Nonresponders often die of therapy-related infections, but occasional individuals die of end-stage pulmonary fibrosis. Lymphomatous transformation is very unusual.

In patients with HIV infections or acquired immunodeficiency syndrome, LIP is part of a spectrum of lymphoid proliferations and demonstrates a virtually identical morphology; however, clinical

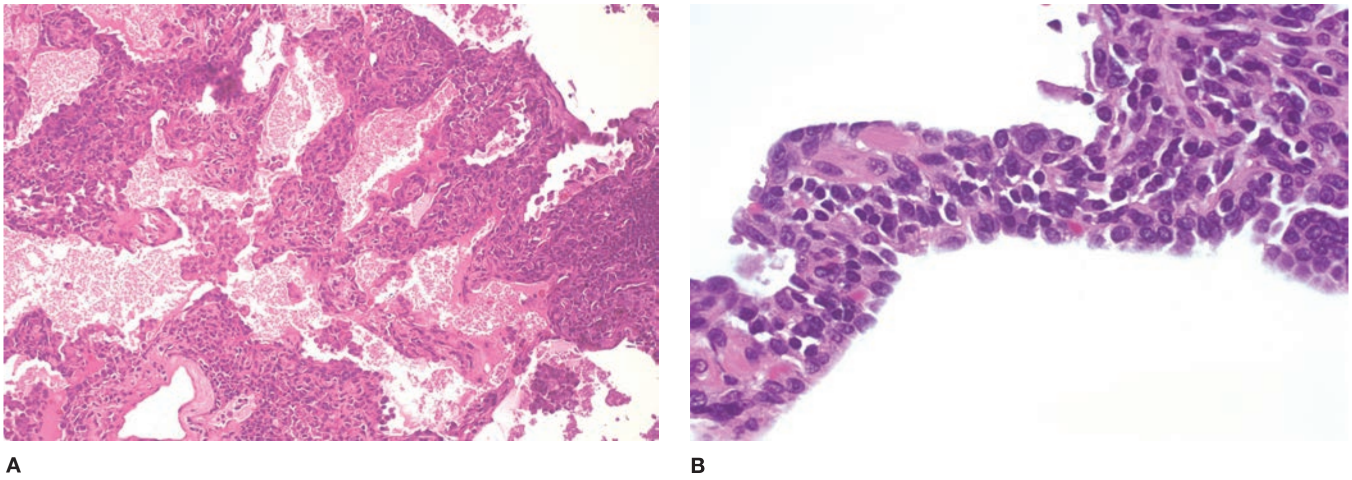

Figure 119-5 **A.** Diffuse alveolar septal expansion with lymphocytes and plasma cells. Hematoxylin and eosin, 50× original magnification. **B.** Higher-power view demonstrating interstitial accumulation of lymphocytes and plasma cells. Hematoxylin and eosin, 60× original magnification.

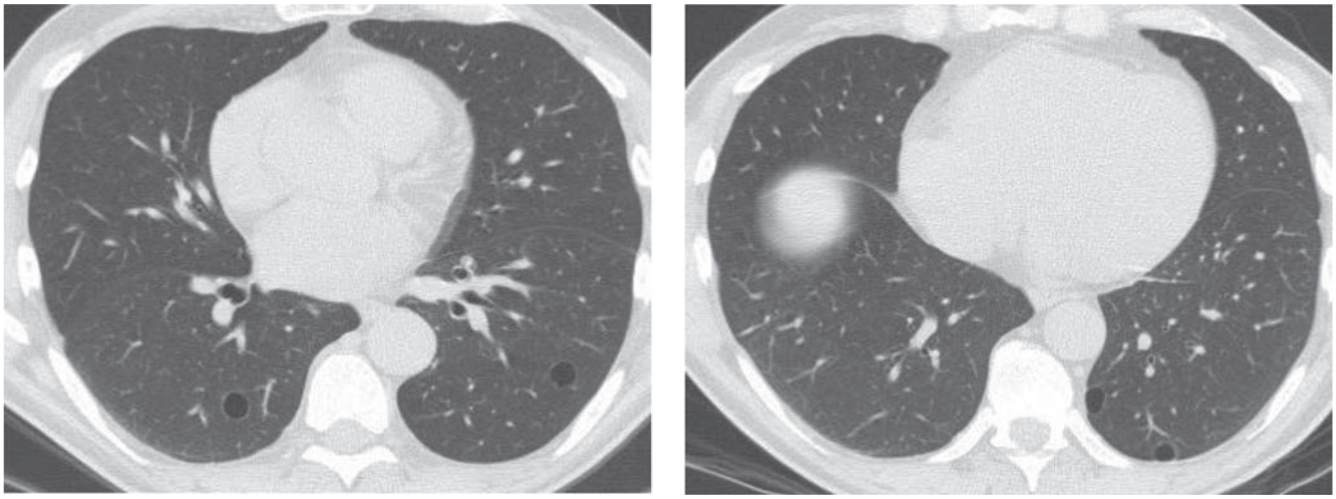

Figure 119-6 Representative CT images from a patient with lymphocytic interstitial pneumonia demonstrating scattered thin-walled cysts.

presentations may differ. Individuals with so-called diffuse infiltrative lymphocytosis syndrome (DILS), featuring sicca syndrome with increased numbers of circulating CD8+ T cells in the blood, generalized lymphadenopathy, and enlarged parotid glands, are at high risk of developing LIP.[36]

■ Granulomatous and Lymphocytic Interstitial Pneumonia

Common variable immunodeficiency syndrome (CVID) is a primary immune disorder with functional abnormalities of the B-cell lineage. Two broad categories of monogenic genetic defects have emerged: mutations in genes that are involved in various stages of B-cell activation, survival, and maturation to plasma cells, and defects in genes that control general immune regulation.[37] There are similarities with a number of other monogenic antibody deficiency syndromes that present with interstitial lung disease having pathology similar to that seen in patients with CVID. These include patients with gain-of-function mutations of PI3KD that develop a CVID-like syndrome defined by lymphoid hyperplasia, which can affect the airways and lung parenchyma.[38]

As a consequence of humoral immune deficiency, patients with CVID suffer from recurrent bacterial infections of the respiratory tract, sepsis with encapsulated organisms, and infections from *Ureaplasma urealyticum*, *Giardia* species, and enteroviruses. Additionally, variable dysfunction of T-cell immunity results in a subset of patients suffering from noninfectious, autoimmune manifestations (cytopenia, hemolytic anemia, neuropathy, endocrinopathies, skin disease, liver disease, uveitis, pernicious anemia), lymphoid lymphoproliferative lesions, and malignancy. In this "autoimmunity" context, lung involvement is characterized by peribronchial and interstitial lymphocytic infiltration, granulomatous inflammation, and organizing pneumonia (so called granulomatous and lymphocytic interstitial pneumonia, or GLILD). Granulomas are also present in hilar and mediastinal lymph nodes.[39] Bronchoalveolar lavage demonstrates a profile very similar to that observed in sarcoidosis. HRCT findings demonstrate a lower lobe predominance and include nodules, smooth thickening of interlobular septa, bronchiectasis, and multifocal pulmonary consolidation (Fig. 119-7). Thoracic adenopathy is consistently present, and splenomegaly is a common feature. PET scan demonstrates hypermetabolic activity in the parenchymal lesions and lymph modes. Diagnosis may be confirmed by transbronchial cryobiopsy or VATS lung biopsy. However, the combination of two clinical parameters (splenomegaly and autoimmune cytopenia), one lung function index ($D_{L_{CO}}$, % predicted), and one immunologic variable (percentage of circulating $CD21^{low}$ B cells) has been recently shown to be a promising tool for early identification of CVID patients with interstitial lung disease, potentially limiting the use of invasive diagnostic procedures.[40]

Milder cases of GLILD may respond to treatment with corticosteroids. For more severe cases, studies have demonstrated a dramatic

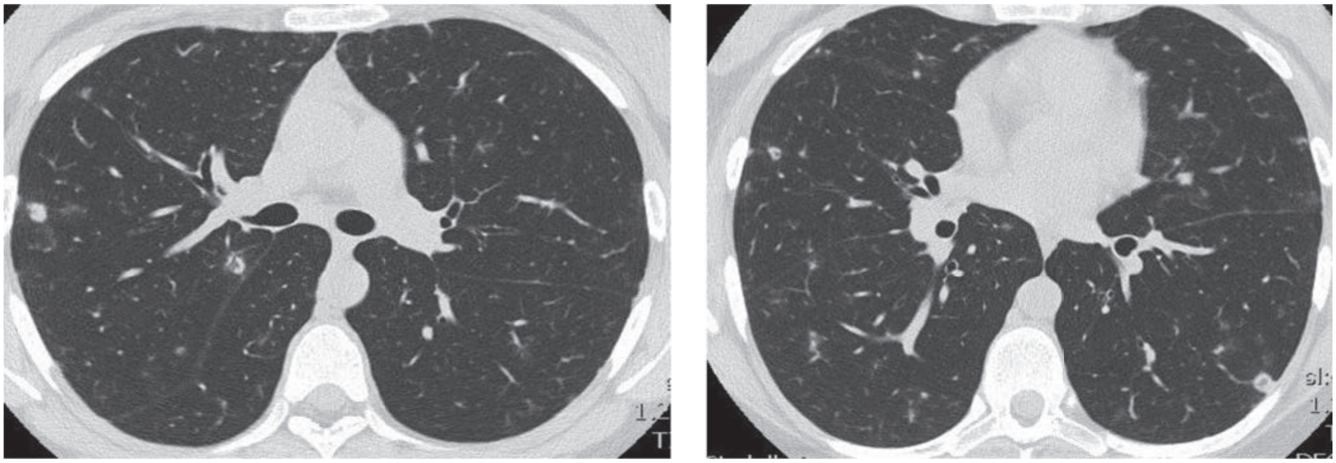

Figure 119-7 HRCT images demonstrating scattered nodules in a 25-year-old female with CVID and GLILD.

response with prolonged remission of disease when a combination of anti-CD20 monoclonal antibody (rituximab) and azathioprine or mycophenolate mofetil was used.[41]

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) is a rare inherited disorder characterized by nonmalignant T- and B-cell lymphoproliferation causing splenomegaly and enlarged lymph nodes; 70% of patients also display autoimmune manifestations, such as autoimmune cytopenias, Guillain-Barré syndrome, glomerulonephritis, uveitis, and hepatitis.[42] A hallmark of ALPS is the presence in peripheral blood of mature alpha/beta T cells that are negative for CD4 and CD 8 (so-called alpha/beta double-negative T cells). Hypergammaglobulinemia, consisting of IgG and IgA, also is frequently observed. The syndrome is caused by a defect in Fas-mediated apoptosis of lymphocytes due to somatic or germline mutation, either heterozygous or homozygous, in FAS, FASLG, or CAPS 8 or 10. ALPS with undetermined genetic defect (ALPS-U) is a term to categorize patients who fulfill the diagnostic criteria of ALPS but who do not have an identifiable mutation despite detailed genetic analysis. ALPS may predispose to malignancies (both non-Hodgkin and Hodgkin lymphomas). Lung abnormalities may be detected mainly in the ALPS-U subtype, and clinical investigation is mainly undertaken when there is suspicion of lymphoproliferative disorders or infections. Patients are asymptomatic or present with dyspnea. Pulmonary function testing often reveals a significant reduction of D_{LCO}. CT scan features are diverse, including ground-glass opacities, large nodules or consolidation, tree-in bud pattern, bronchiectasis, septal thickening, cysts and cavities, and mediastinal adenopathy. BAL fluid lymphocytes are significantly increased. Histopathologic features are a mix of mucosal lymphoid hyperplasia/follicular bronchiolitis, bronchiectasis, interstitial lymphocytic infiltration, interstitial fibrosis, organizing pneumonia, acute inflammation, and granulomatous changes.

Recently the mTOR inhibitor rapamycin (sirolimus) was shown to be highly effective in amelioration of ALPS-related refractory cytopenias in a small multicenter clinical trial.[43]

Castleman Disease

Castleman disease (CD) is the eponymous term used to describe a group of at least four disorders that share a spectrum of characteristic histopathologic features but have a wide range of etiologies, presentations, treatments, and outcome.[44,45] The clinical presentation is divided into unicentric (UCD) and multicentric (MCD) subtypes. Histologic features clearly defined in lymph nodes specimens range from forms characterized by numerous follicles with regressed germinal centers, prominent vascularization (a peculiar feature is represented by vessels penetrating germinal centers conferring a “lollipop appearance”), and large dysplastic cells with vesicular nuclei expressing markers of follicular dendritic cells (CD21+, CD23+ cells) (the hypervascular end of the spectrum) (Fig. 119-8) to forms in which hyperplastic and, occasionally, regressed germinal centers with prominent monotypic or polyclonal plasmacytosis in the interfollicular areas are evident (plasma cell variant) (Fig. 119-9). Overlapping features of both types represent mixed histopathology. Recently, the Castleman Disease Collaborative Network proposed a classification system that retained the UCD and MCD nomenclature, but further divided MCD by etiologic driver (HHV-8–associated MCD, POEMS-associated MCD, idiopathic MCD [iMCD], and within iMCD, by phenotype, iMCD-TAFRO [thrombocytopenia (T), anasarca (A), fevers (F), reticulin myelofibrosis (R), organomegaly (O)], and iMCD not otherwise specified).[45] Each variant is associated with a wide range of clinical features; histopathology should be used to determine whether a patient has CD, but it does not alone guide clinical management.[46]

UCD is an uncommon form of lymphoid hyperplasia in young to middle-aged individuals of either gender that primarily affects mediastinal, retroperitoneal, and cervical lymph nodes (Fig. 119-10). Pleural, chest wall, and extrathoracic involvement have been reported, but pulmonary parenchymal disease is a true rarity, and most reported cases likely represent nodal, rather than true pulmonary, disease.[47,48] UCD lesions are usually asymptomatic or rarely cause compression-related symptoms. Rare severe complications, such as polyneuropathy, autoimmune hemolytic anemia, and paraneoplastic autoimmune multiorgan syndrome with severe obstructive pulmonary impairment, however, may be observed. Laboratory tests are usually normal, but anemia, hypergammaglobulinemia, and elevated sedimentation rate may be present. PET may be positive with low SUV. Some 70% of UCDs feature hyaline-vascular morphology (HV-CD), whereas the remainders are the plasma cell variant. UCD is considered most likely to be a clonal neoplastic process with the follicular dendritic cell as the progenitor. In fact, secondary follicular dendritic cell sarcomas are not an uncommon complication.[2]

Surgical excision is the treatment of choice and results in the disappearance of associated symptoms.[49] Neoadjuvant therapy with rituximab or siltuximab/tocilizumab (if evidence of acute

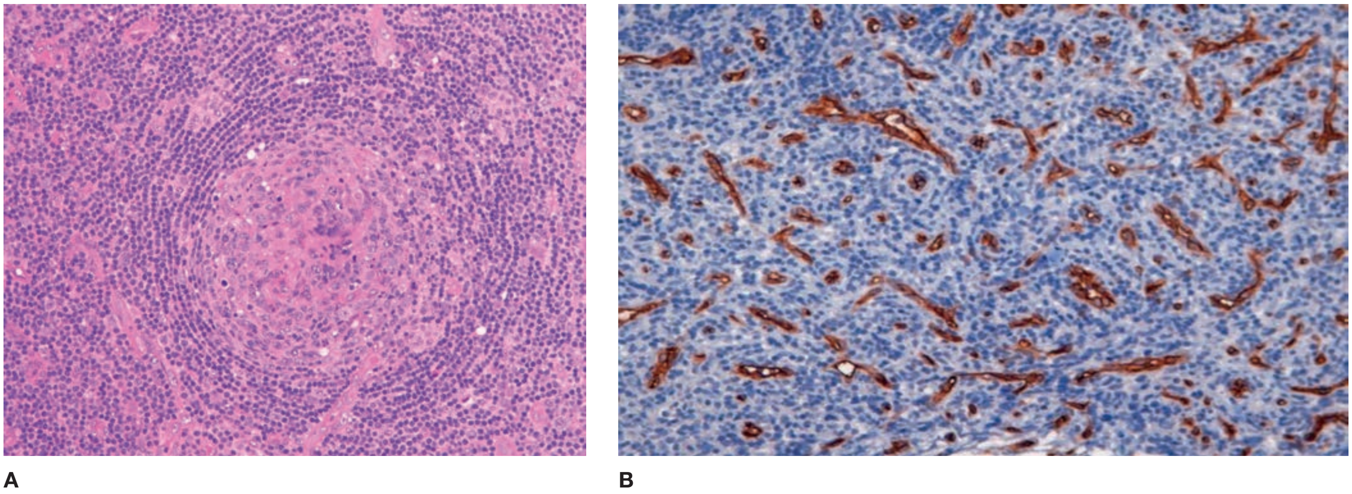

Figure 119-8 Hyaline-vascular Castleman disease. **A.** Biopsy demonstrating prominent mantle lymphoid cells with characteristic “onion-skin” pattern around the atrophic germinal center with hyalinized penetrating venules resulting in “lollipop” appearance (H&E, × 10). **B.** Vascular proliferation with increased numbers of high endothelial venules marked by CD34 monoclonal antibody (× 20)

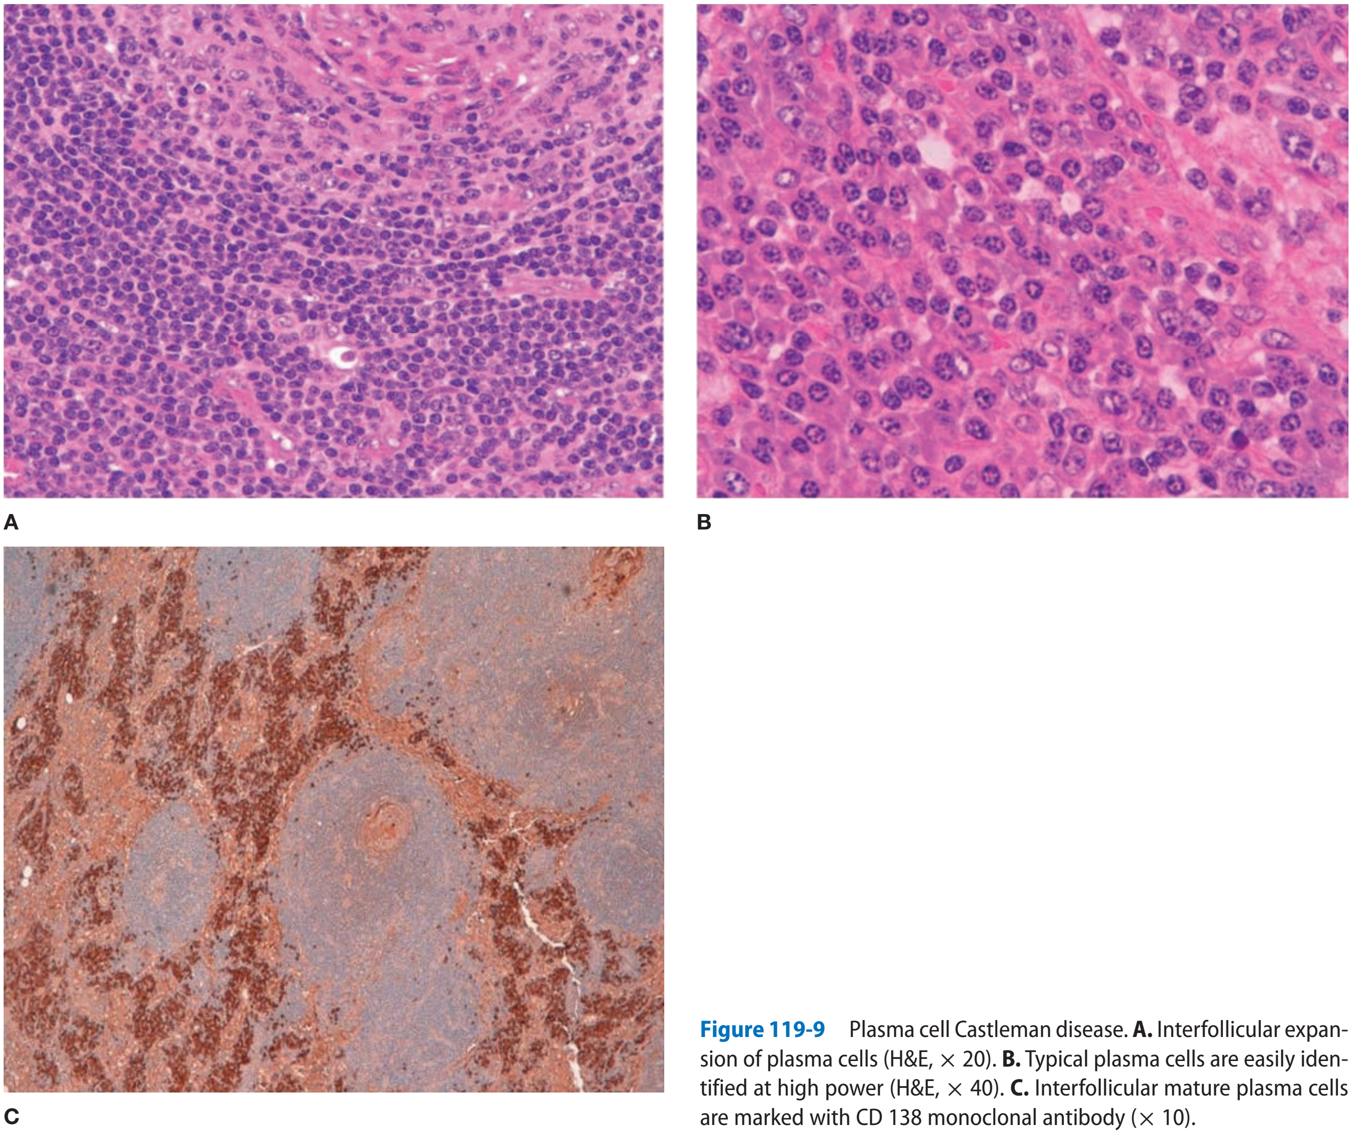

Figure 119-9 Plasma cell Castleman disease. **A.** Interfollicular expansion of plasma cells (H&E, × 20). **B.** Typical plasma cells are easily identified at high power (H&E, × 40). **C.** Interfollicular mature plasma cells are marked with CD 138 monoclonal antibody (× 10).

inflammatory state is documented) may be considered.[49] Radiation also may be effective as primary therapy.[49]

MCD is, as already mentioned, a heterogenous group of disorders. Inclusion (major and minor) criteria and exclusion criteria to formulate a diagnosis have been formalized.[45] Uncontrolled HHV-8 infection is the etiologic driver in HHV8-MCD, with viral-induced transcription of homolog interleukin 6 (IL-6) that subsequently incites lymph nodes, extranodal pathology, and signs and symptoms.[50] HHV8-MCD is quite common in HIV-positive subjects. Monoclonal plasma cells are the likely etiologic drivers of polyneuropathy, organomegaly, endocrinopathy, skin changes (POEMS)-MCD.[51] Excessive VEGF and IL-12 production are pivotal pathogenetic steps in this subtype. The etiology and pathogenesis of idiopathic MCD are less well understood. IL-6 is a critical disease driver in most patients. Recently, a key role of activated T cells and mammalian target of rapamycin pathway activation has been observed.[52]

Patients with MCD exhibit a wide spectrum of clinical and laboratory abnormalities that sometimes follow a waxing and waning course. Symptoms and signs include fever and asthenia; ascites and peripheral edema; cytopenias; hemophagocytic syndrome; liver and kidney dysfunction, including secondary amyloidosis and membranoproliferative glomerulonephritis; peripheral neuropathy; and skin abnormalities (rash, hyperpigmentation, cherry angiomata).

TABLE 119-2 Diagnostic Criteria for iMCD-TAFRO

Histopathology (all needed):

- Typical lymph node pathology (atrophic germinal centers with enlarged nuclei of endothelial cells)
- Proliferation of endothelial venules
- Small numbers of mature plasma cells
- Negative LANA-1 for HHV-8

Major clinical-laboratory criteria (need 3 of 5):

- Thrombocytopenia
- Anasarca
- Fever
- Reticulin fibrosis in bone marrow biopsy
- Organomegaly

Minor criteria (need at least one):

- Hyper/normoplasia of megakaryocytes
- High alkaline phosphatase without markedly elevated transaminases

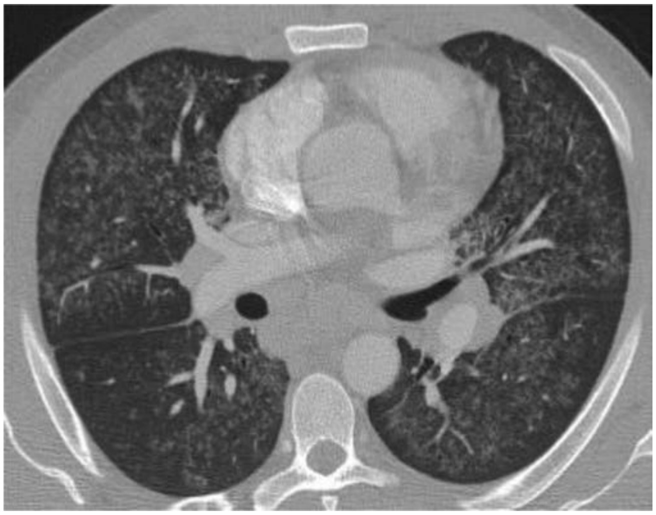

Figure 119-12 HHV-8–associated multifocal Castleman disease in a 37-year-old male with HIV. Axial CT scan demonstrates bilateral, extensive centrilobular and peribronchovascular ground glass nodules, mainly in the mid and upper zones, with subpleural sparing. Mediastinal and hilar adenopathy also is present.

Positive testing for HHV8 by LANA-1 on biopsy specimens and/or polymerase chain reaction for HHV8 in blood establish the diagnosis of HHV8-MCD. iMCD is clinicopathologically similar to HHV8-MCD, but the viral agent is not detectable. iMCD-TAFRO is an aggressive clinical subtype. Diagnostic criteria for iMCD-TRAFO are reported in Table 119-2.

Lung involvement in MCD is characterized by marked accumulation of lymphocytes and plasma cells (with sheets of plasma cells without intervening lymphocytes), lymphoid follicles, and dense fibrosis mainly in the alveolar area adjacent to interlobular septa, bronchovascular bundles, and pleura and the absence of obstructive vasculitis or eosinophilic infiltrates[53] (Fig. 119-11). A pattern mimicking LIP is more frequently observed in HHV8-MCD.

CT scan findings of lung involvement are usually characterized by septal and peribronchovascular thickening, intralobular reticulation, and centrilobular nodules with ground glass attenuation (Fig. 119-12). Nodules and cysts also have been reported. Bilateral pleural effusions are typically observed in TAFRO syndrome. Enlarged lymph nodes in the hila and mediastinum are almost always documented.

The main therapeutic options for treatment of MCD include corticosteroids, immunosuppressive drugs (cyclosporine A, cyclophosphamide, thalidomide, bortezomib, lenalidomide), rituximab, rituximab combined with etoposide or liposomal doxorubicin, and anti–IL-6 drugs (e.g., siltuximab, tocilizumab). Sirolimus may be useful in cases of mTOR activation.[54,55] JAK inhibitors could be considered in siltuximab nonresponders. In bronchiolitis obliterans, a severe complication mainly observed in the stroma-rich variant of the hyaline vascular Castleman disease subtype, lung transplantation may represent a therapeutic option.[56]

■ Immunoglobulin G4–Related Lung Disease

IgG4-related disease (IgG4-RD) is an immune-mediated disorder associated with fibroinflammatory mass–forming lesions that can occur at nearly any anatomic site. It follows a biphasic progression characterized by an "inflammatory" phase that eventually

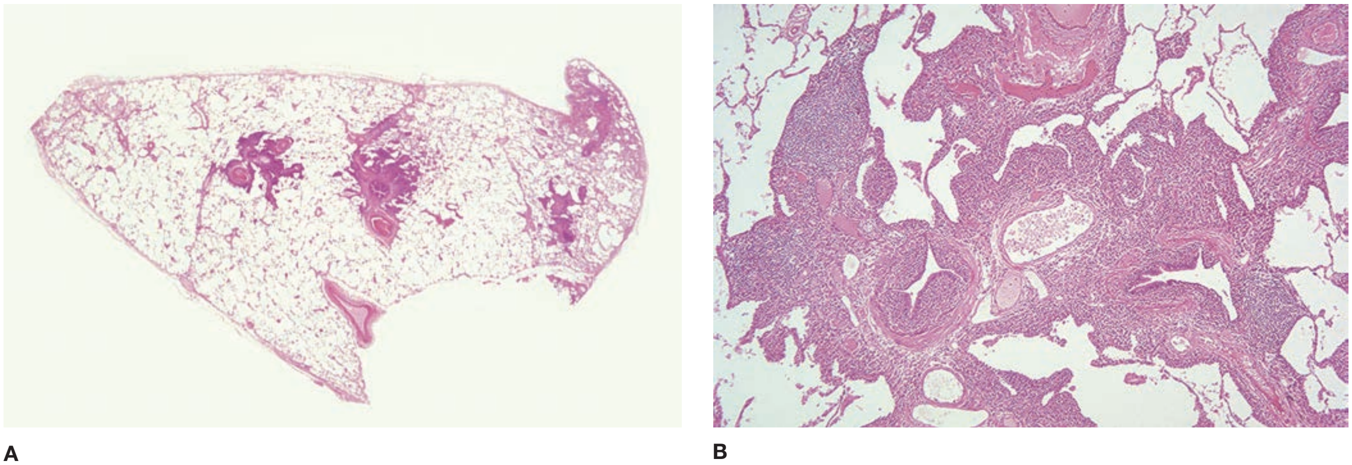

Figure 119-11 Multicentric Castleman disease. **A.** The bronchocentric nature of this KSHV/HHV8-driven systemic process is apparent at scanning microscopy. Hematoxylin and eosin, 1× original magnification. **B.** The lymphoplasmacytic infiltrate is confined to the pulmonary interstitium. Honeycomb-like changes may develop. Hematoxylin and eosin, 10× original magnification. *(Glass slides reproduced with permission from Dr. J. English, University of British Columbia and Vancouver Hospital, Vancouver, BC.)*

TABLE 119-3 Diagnostic Criteria for IgG4-RD

Clinical and radiologic features compatible with IgG4-RD
Characteristic histopathologic and immunostaining features
• Dense lymphoplasmacytic infiltrates
• Storiform pattern of fibrosis
• Obliterative phlebitis
• Increased number of IgG4+ plasma cells and IgG4+/IgG+ cell ratio >40%
Other supportive findings
• Serum IgG4 level >135 mg/dL
Exclude other identifiable diseases with overlapping clinicoradiologic and/or histopathologic features

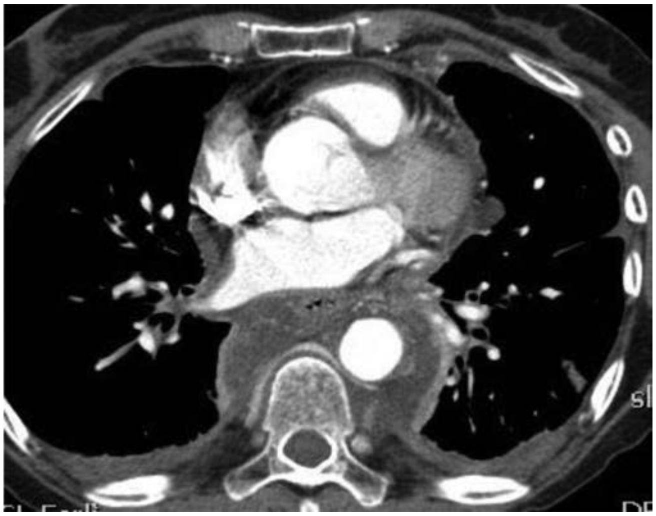

Figure 119-13 IgG4-related lung disease. CT scan with contrast showing soft tissue enlargement of the retromediastinal and pleural space.

culminates in a “fibrotic” outcome and often presents as a multiorgan disease that may be confused with malignancy, infection, or other immune-mediated conditions, such as Sjögren syndrome, ANCA-related vasculitides, or rarer autoinflammatory disorders. Although the pathogenesis of IgG4-RD is still poorly understood, there is a growing body of evidence that indicates an antigen-driven process requiring T-cell and B- cell interaction in which autoantibodies, plasmablasts, follicular helper T cells, and CD4+ cytotoxic T lymphocytes participate.[57,58]

Well-characterized IgG4-RD manifestations include relapsing pancreatitis, sclerosing cholangitis, retroperitoneal fibrosis/aortitis, hypertrophic pachymeningitis, and chronic sialadenitis. According to the main clinical manifestations, laboratory profile, and sites involved, four clinical phenotypes have been identified: pancreato-biliary; retroperitoneal/aortitis; head and neck limited; and Mikulicz/systemic. Males predominate in all but the head and neck phenotype that more frequently is observed in Asian females.

Criteria for diagnosis and classification have been recently revised[59] (Table 119-3). Definitive diagnosis requires rigorous clinicopathological correlations because clinical assessments, laboratory tests, and imaging studies are often insufficient.[60] Erythrocyte sedimentation rate, LDH, and soluble IL-2 receptors may be elevated; C-reactive protein is usually normal. Peripheral blood eosinophilia and increased serum IgE levels occur in almost 30% of patients.[61] Circulating autoantibodies, such as antinuclear antibodies and rheumatoid factor, may be present. An increase of serum IL-6 has been described. Although useful for initial screening, elevation of serum IgG4 has poor diagnostic utility because it may occur in a variety of neoplastic, infectious, and autoimmune disorders. Increased ratios of serum IgG4 to total IgG (>10%) or IgG1 (>24%) have been shown to improve diagnostic specificity, especially when IgG4 concentrations are only slightly raised. Ultimately, pathologic examination plays a pivotal role in achieving a definite diagnosis.

Lungs, pleura, and large airways are affected mainly in the Mikulicz/systemic phenotype.[62] Lung/pleural/large airways involvement may represent the first manifestation of the disease. Most patients are males with an average age of 69 years. One-half of patients have respiratory symptoms such as cough, exertional dyspnea, and chest pain. Very rarely recurrent wheezing or inspiratory stridor are the first manifestations. Low-grade fever and weight loss may be less frequently observed. No risk factors are recognized.

Radiographic presentation varies considerably. Major subtypes of CT features have been identified:[61] solid nodular lesions; round-shaped ground-glass opacities; alveolar-interstitial type with honeycombing, bronchiectasis, and diffuse ground glass; and bronchovascular type with thickening of the bronchovascular bundles and interlobular septa. Masses and large nodules are usually solitary, whereas small nodules are multiple. Most patients have more than one abnormality. Hilar and mediastinal adenopathy may be seen. Pleural thickening and/or effusion and thickening of the wall and stenosis of the lumen of the larger airways also have been reported (Fig. 119-13). Abnormal uptake on 18-fluorodeoxyglucose PET is usually present. Bronchoscopic inspection of the airways is usually unremarkable, but multiple white nodular protuberances, along with mucosal hyperemia and edema or subglottic stenosis, have been described.

The three major histopathologic features defined in soft tissue, pancreas, or other sites are (1) dense lymphoplasmacytic infiltrate; (2) fibrosis, arranged, at least focally, in a storiform pattern; and (3) obliterative phlebitis.[63] IgG4-related pulmonary disease may lack all the distinct storiform fibrosis, while pulmonary arteries, in addition to veins, may be involved. Notably, lung biopsy interpretation of this condition is often challenging because of a relative paucity of pathognomonic features and the presence of a plethora of findings overlapping with other fibroinflammatory processes.[64] The most notable and consistent histopathologic finding in lung biopsies is a prominent lymphangitic distribution of plasma cell–rich inflammatory infiltrates, with involvement of visceral pleura, interlobular septa, and bronchovascular stroma. Additionally, vascular changes without vessel lumen obliteration, concentric bronchiolar inflammatory infiltration with germinal centers, and organizing pneumonia and/or prominent eosinophilia may be seen.

Tissue and serum IgG4 and IgG levels serve as supplemental diagnostic data. Immunohistochemical stain evaluation requires counting the three 40× microscopic fields with the highest number of IgG4+ plasma cells, in addition to counting the number of IgG+ plasma cells in those same areas. According to the consensus statement, more than 50 IgG4+ cells per high-power field and more than 20 IgG4+ cells per high-power field are adequate cutoffs in surgical and nonsurgical lung biopsies, respectively.[65] The IgG4+/IgG+ plasma cell ratio should be greater than 40%. However, other lung processes, including idiopathic NSIP, usual interstitial pneumonia, Rosai Dorfman disease, and connective tissue disease–associated interstitial pneumonias, as well as inflammatory myofibroblastic tumor, may have increased IgG4+ cell counts in biopsy specimens.

Glucocorticoids (0.6–1 mg/kg daily of oral prednisone or equivalents) represent the cornerstone for inducing disease remission in patients with active IgG4-RD, both at disease onset and with disease flare. Although no consensus exists on the optimal duration of steroid treatment and on the pace of steroid tapering, one accepted

TABLE 119-4 Classification of Primary Pulmonary Lymphoid Malignancies

Lymphomas involving mainly the lungs
MALT lymphomas of the lung
Follicular lymphoma
Diffuse large B-cell lymphomas
Lymphomatoid granulomatosis
Intravascular large B-cell lymphoma of the lung
Plasmacytoma
Amyloidosis
Light chain disease of the lung
Extranodal natural killer T-cell lymphoma (nasal type)
Peripheral T cell lymphoma, not otherwise specified (NOS)
Anaplastic large cell lymphoma (ALCL)
Hodgkin lymphoma
Pleural lymphomas
Primary effusion lymphoma
Pyothorax-associated lymphoma

approach is to maintain the starting dose for 2 to 4 weeks and then gradually reduce by 5 mg every 2 weeks over a period of 4 to 6 months. Immunosuppressive drugs such as azathioprine, methotrexate, cyclophosphamide, leflunomide, mycophenolate mofetil, cyclosporine, and tacrolimus have been used. Emerging treatment options include rituximab, bortezomib, belimumab, abatacept, and elotuzumab.[66]

PRIMARY PULMONARY LYMPHOID MALIGNANCIES

Primary lymphoid neoplasms are classified according to the general WHO classification system (Table 119-4). Although more than half of patients with nodal lymphoma have lung involvement, primary pulmonary lymphomas constitute less than 0.5% of primary lung neoplasms.[67,68] Furthermore, the most common primary lung lymphoma, marginal zone non-Hodgkin lymphoma of MALT origin, represents less than 10% of extranodal lymphomas.[69] Hodgkin lymphomas (HL) are only rarely considered lung primaries, even when the lung is the principal site of organ involvement.[70,71] Furthermore, mainly in primary MALT pulmonary lymphoma, if in-depth investigations are done, other extranodal sites (e.g., stomach, colon, thyroid, bone marrow) may be identified as sites of subclinical clonal lymphoid proliferation.[1,2]

■ Extranodal Marginal Zone B-Cell Lymphoma of MALT Type

MALT lymphoma is the most common type of primary pulmonary lymphoma, accounting for 70% to 90% of all cases.[72,73] It usually affects patients in their seventh decade of life with a slight female predominance. Autoimmune diseases, mainly Sjögren syndrome, are present in approximately one-third of cases. Approximately 40% of patients are asymptomatic, with the remaining presenting with systemic or organ-related symptoms, such as fever, night sweat, malaise, cough, dyspnea, and even less frequently, hemoptysis and chest pain. Serum findings include monoclonal gammopathy detected in up to 60% of patients. Other nonspecific laboratory findings are elevated LDH, C-reactive protein, and beta-2 microglobulinemia. CT findings vary and include alveolar consolidation with air bronchograms, areas of ground-glass attenuation, nodules, cysts, or thickening of the interlobular septa (Fig. 119-14A).[74] Areas of calcification/ossification indicate the coexistence of amyloid deposits (Fig. 119-14B). Bronchiectasis often can be seen in larger lesions. These abnormalities are frequently multiple and bilateral. The disease may rarely appear as a submucosal lesion in the large airways or as a pleural effusion. Hilar and mediastinal lymphadenopathy is not a prominent radiologic finding, and only 30% of cases exhibit nodal involvement at pathologic analysis. PET-CT is often positive.

Under light microscopy, pulmonary MALT lymphoma shows lymphocytes disrupting the lung architecture.[1,2,72] Such lesions display a spectrum of architectural patterns, ranging from discrete nodular lesions with variably defined borders to a lymphangitic-type distribution along the visceral pleura, interlobular septa, and around bronchovascular bundles (Fig. 119-15). Rarely, it may manifest predominantly as an endobronchial lesion.

The classic histologic "triad" of MALT lymphoma consists of reactive germinal centers, diffuse infiltration by centrocyte-like lymphocytes, and lymphoepithelial lesions (lymphocytes in nests infiltrating the bronchiolar epithelium). The neoplastic cells are heterogeneous and are thought to derive from a single precursor cell

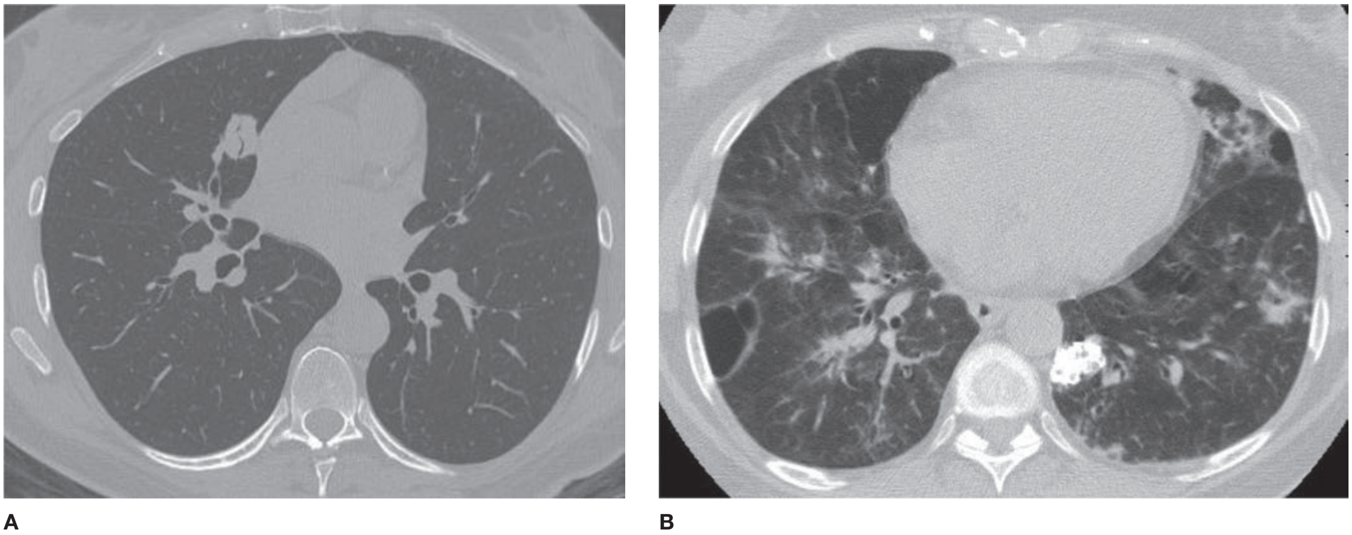

Figure 119-14 Primary pulmonary MALT lymphoma. **A.** Axial CT scan demonstrating a nodule with air bronchogram. **B.** Scattered bilateral areas of alveolar consolidation accompanied by cysts and a calcified nodule representing an amyloid deposit.

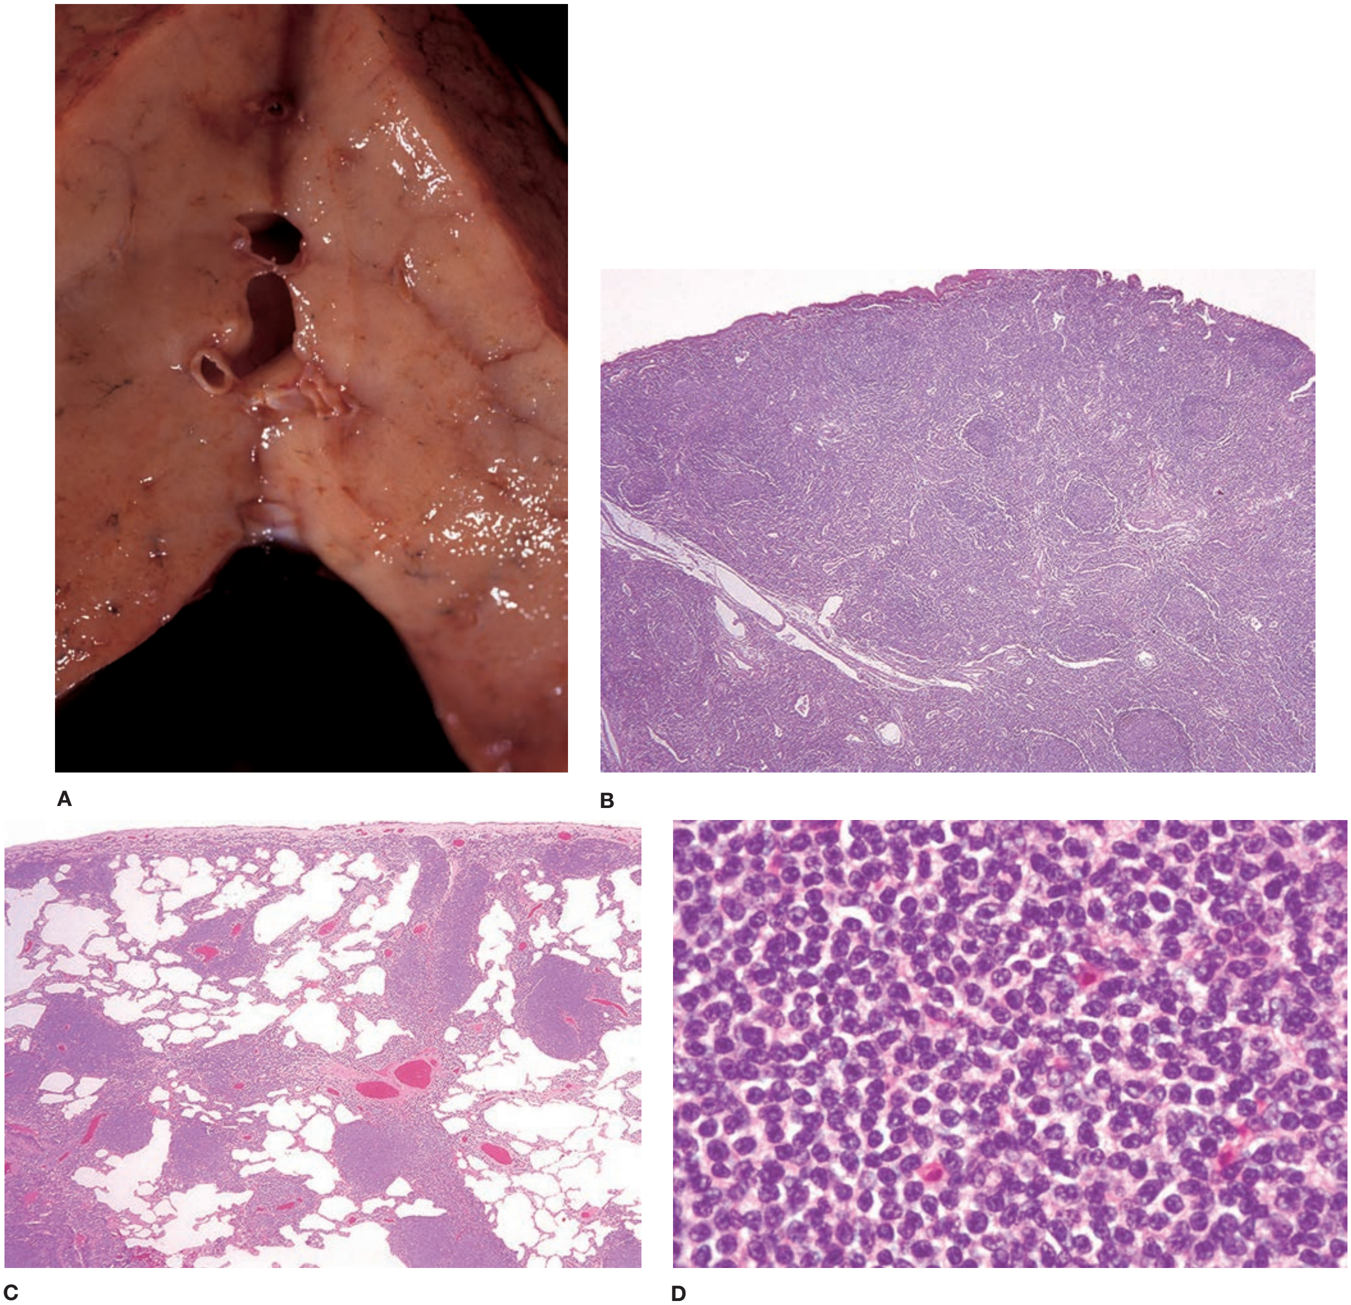

Figure 119-15 Extranodal marginal zone B-cell lymphoma of MALT type. **A**. Tan fleshy tumor fills alveolar spaces but preserves lobular architecture. **B.** Malignant lymphoid cells overrun lung tissue. Germinal centers are usually prominent. Hematoxylin and eosin, 4× original magnification. **C.** Malignant lymphoma often tracks along lymphatic pathways beyond the dominant mass lesion. Involvement of visceral pleura suggests the malignant nature of the process. Hematoxylin and eosin, 4× original magnification. **D.** Most pulmonary marginal zone B-cell lymphomas of MALT type are composed of small monotonous round (centrocyte-like) B-lymphocytes. Hematoxylin and eosin, 40× original magnification.

with multilineage potential. They include (1) small centrocyte-like lymphocytes with round, regular to indented, "cleaved" nuclei, evident nucleoli, moderately dispersed chromatin, and scant cytoplasm; (2) monocytoid lymphocytes with moderately condensed chromatin, inconspicuous nucleoli, and more abundant amphophilic-to-pale eosinophilic cytoplasm forming a perinuclear halo; and (3) a variable amount of plasmacytoid lymphocytes and plasma cells. Erosion of the bronchial cartilage and vascular involvement are frequent findings. Nonnecrotizing epithelioid granulomas, occasional massive crystal-storing histiocytosis, mostly in overt plasmacytic differentiation, large lamellar bodies (rings of eosinophilic proteinaceous material) within the spared alveoli, and multinucleated giant cells may be observed.

Pulmonary MALT lymphomas with prominent plasmacytic differentiation show a frequent association with amyloidosis, paraproteinemia, and light and/or heavy chain deposition. This MALT lymphoma subset is most common in elderly women (mean age, 70 years) with underlying autoimmune disorders, such as Sjögren syndrome or RA. Typically, MALT lymphoma cells express CD19, CD20, CD22, and CD79a and are negative for CD3, CD5, CD10, CD23, BCL6, and cyclin D1. A small immunohistochemistry panel is desirable to exclude follicular lymphoma, mantle cell lymphoma, and chronic lymphocytic leukemia. BCL2 staining is an adjunct in distinguishing neoplastic cells from reactive monocytoid lymphocytes. Cytokeratin immunostaining supports the identification of lymphoepithelial lesions. The Ki-67 proliferation index is low in the neoplastic cells (<10%) but is typically higher in residual germinal centers. Kappa and lambda light chain restriction of plasma cells and/or B lymphocytes by flow cytometry, immunohistochemistry, or in situ hybridization may be necessary to support the diagnosis.

Up to 50% of MALT lymphomas carry a chromosomal translocation resulting in the production of a chimeric protein (BIRC3-MALT1) and in transcriptional deregulation of BCL10, MALT1, and FOXP1, with variable frequencies, depending on the site of occurrence. In both pulmonary and gastric MALT lymphoma, the most common cytogenetic abnormality is t(11;18)(q21;q21) (present in 31%–53% of cases), which generates a fusion transcript, resulting in activation of the NF-kB pathway, which is a potential therapeutic target. Trisomy 3 (20% of cases), t(14;18)(q32;q21) (IGH-MALT1) (up to 10%), and trisomy 18 and t(1;14)(p22;q32) (BCL10-IGH) (both up to 7%) may occur with decreasing frequency. Other genetic alterations, such as abnormalities of TNFAIP3 on chromosome 6q23, which may include deletions, mutations, and promoter methylation, have been reported in 15% to 30% of cases. MYD88 L265P mutations may occur in a minority of cases of MALT lymphoma (6%–9%) at different sites, including lung. Additional genetic alterations assessed by next-generation sequencing analysis, involving chromatin remodeling, BCR/NF-kB and NOTCH pathways, and recurrent inactivations of TET2, have been recently described.

Diagnosis of MALT lymphoma usually requires biopsy; transbronchial cryobiopsy, or percutaneous CT- or echo-guided core biopsy are often sufficient. In cases in which alveolar consolidation is present, bronchoalveolar lavage may document a B-cell lymphocytosis consisting of atypical cells with light chain monotypic restriction on flow cytometry.[75] Surgical lung biopsy is the definitive approach when less invasive techniques have failed to provide a diagnosis.

Treatment includes surgical resection of localized lesions and radiotherapy, chemotherapy, or immunotherapy in nonresectable cases, depending on patient comorbidities.[72] Administration of rituximab may result in long-term remission, yielding a response rate as high as 70%, but it is associated with disease recurrence in up to 36% of cases. The combination of rituximab plus chemotherapy yields higher response rate and event-free survival according to some studies.[76] Systemic therapy is the current treatment of choice for advanced or multicentric primary pulmonary MALT lymphoma. Novel therapeutic strategies include ibrutinib, a Bruton tyrosine kinase inhibitor, and the PI3K inhibitors copanlisib and umbrasilib.[72] The presence of confluent sheets or large aggregates of large B cells points toward a transformation to diffuse large B-cell lymphoma (DLBCL) in up to 20% of cases and is associated with a poorer prognosis, prompting a change in the treatment protocols.

Major prognostic factors associated with survival are age, performance status, disease stage, presence of systemic symptoms, coexistence of autoimmune disorders, number and location of pulmonary lesions, presence of paraproteinemia, and type of treatment. An associated pleural effusion or amyloid portends a poorer prognosis. An elevated β2-microglobulin level and stage IV classification have been reported as independent predictors of prognosis for MALT lymphoma occurring at all sites.

■ Follicular Lymphoma

Follicular lymphoma is generally an indolent B-cell lymphoproliferative disorder of transformed follicular center B cells. It is characterized by diffuse lymphadenopathy, bone marrow involvement, splenomegaly, and, less commonly, other extranodal sites of involvement such as gastrointestinal tract, lung, skin, and other sites.[1] It affects adults (median age, 59 years) and it is more frequent in females (male:female ratio, 1:1.7). In general, cytopenias can occur but constitutional symptoms of fever, night sweats, and weight loss are uncommon. Primary lung involvement is rare and usually asymptomatic. HRCT scan shows ground-glass opacities sometimes with a "crazy paving" pattern or nodules. The differential diagnosis includes minimally invasive or in situ adenocarcinoma. Diagnosis is based on histology and often requires large biopsy specimens. Immunohistochemical staining is positive in virtually all cases for cell-surface CD20 and CD10, nuclear staining for Bcl6 and monoclonal immunoglobulin, as well as membrane expression of bcl-2 protein. The overwhelming majority of cases have the characteristic translocation t(14;18)(q32;q21) involving the IgH/bcl-2 genes. The majority of patients are treated with chemotherapy plus rituximab, which has improved response rates.

■ Diffuse Large B Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) as a group is the second most common type of primary pulmonary lymphoma, usually affecting older adults in the sixth and seventh decades.[1,2,76] Morphologic, biologic, and clinical studies have subdivided DLBCL into morphologic variants, molecular subtypes, and distinct disease entities.[77] The main morphologic variants are centroblastic, immunoblastic, and anaplastic. The molecular subtypes are germinal center, B cell, and activated B cell. However, there remain many cases that may be biologically heterogeneous.

The centroblastic variant is characterized by cells with oval to round vesicular nuclei, multiple nuclear membrane–bound nucleoli, and scanty pale cytoplasm. The immunoblastic variant contains large lymphoid cells with round to oval vesicular nuclei and a single centrally located prominent nucleolus with scant to moderate basophilic cytoplasm (Fig. 119-16A). In some cases, plasmacytic differentiation may be seen, with eccentrically located nuclei. The anaplastic variant is characterized by large pleomorphic cells with bizarre irregular nuclei, often with multinucleated forms, and variable amounts of cytoplasm. Lymphoma cells are positive for CD20, CD79a, PAX5, CD10 (30%–50% of cases), BCL6 (60%–90% of cases), MUM1 (35%–65% of cases), BCL2 (47%–84% of cases), and CD5 (5%–10% of cases). Some DLBCL cases, especially the anaplastic variant, are positive for CD30. Ki67 staining is usually positive in greater than 40% of neoplastic cells (and in some cases, this value may exceed 90%). Cases that are CD10+ are classified as a germinal center B-cell subtype; this also applies to cases that are CD10− but BCL6+ and MUM1−. BCL6(3q27) rearrangement is seen in ≤30% of DLBCL. Approximately 20% to 0% of DLBCL cases have t(14;18) involving the BCL2 gene. MYC rearrangement occurs in approximately 8% to 14% of DLBCL cases. Cases with MYC and BCL2 and/or BCL6 rearrangement are called "double/triple-hit lymphomas" and are classified in a separate category of "high-grade B-cell lymphoma with MYC and BCL2 and/ or BCL6 rearrangement." In a minority of cases, markers for EBV infection may be detected (EBV-positive DLBCL not otherwise specified).

DLBCL manifests as a primary lung disease, most frequently with a nodule or a large mass, sometimes occupying most of a lobe and often accompanied by foci of necrosis. The pattern of growth is intraparenchymal or endobronchial (Fig. 119-16B), although it may appear with pleural effusion and pleural masses. PET positivity is the rule. Symptoms include cough, hemoptysis, low-grade fever, and asthenia. Laboratory tests are nonspecific, and diagnosis requires a biopsy; small samples are usually enough. Treatment is with an R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and steroids) regimen; the 5-year progression-free and overall survival rates were found to be approximately 60% and 65%, respectively. Chimeric antigen receptor (CAR) T-cell immunotherapy has been recently found to be an effective treatment in relapsed and refractory patients.[78]

■ Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) is characterized by an angiocentric/angiodestructive polymorphous lymphoid infiltrate composed of EBV-positive B cells admixed with a large number of

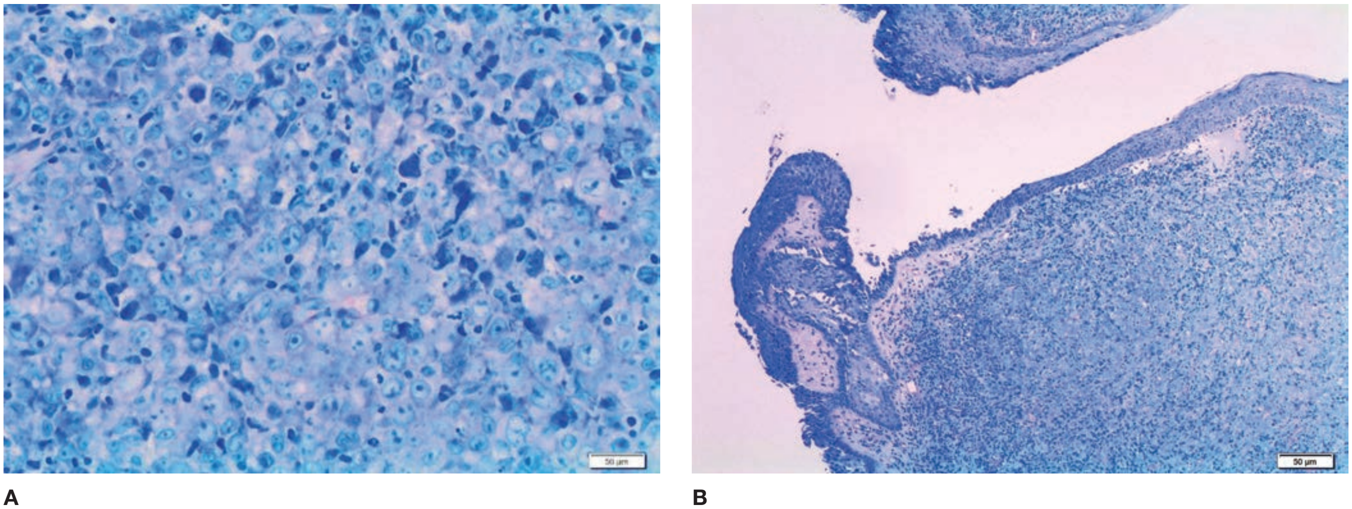

Figure 119-16 Pulmonary diffuse large B-cell lymphoma, immunoblastic variant. **A.** Sheet of large lymphoid cells with round to oval vesicular nuclei and a single centrally located prominent nucleolus with scant to moderate basophilic cytoplasm (Giemsa, × 40). **B.** Pulmonary diffuse large B-cell lymphoma arising in a large airway. Neoplastic cells infiltrating the submucosa (Giemsa, × 10).

reactive T cells. LYG is considered an EBV-driven B-cell lymphoproliferative disorder arising in individuals with either obvious or clinically undetected defects in cell-mediated and, perhaps, also humoral immunity.[1,2,72] Predisposing conditions include Wiskott–Aldrich syndrome, HIV infection, and X-linked lymphoproliferative syndrome. LYG has been reported in patients with autoimmune disorders who underwent long-term methotrexate or azathioprine therapy. Patients presenting without evidence of underlying immunodeficiency usually manifest reduced immune function on careful clinical or laboratory analysis.

Although quite rare, LYG has characteristic clinical features.[79–81] Patients usually present in the fifth or sixth decades of life, but children and the elderly can be stricken. Men are affected two to three times as often as women. Dyspnea, cough, and chest pain, along with fever, malaise, and weight loss, are the most common presenting complaints; up to 40% of patients also have skin nodules, ulcers, rashes, peripheral neuropathies, or symptoms referable to central nervous system involvement. Other sites that may be involved are adrenal glands, prostate, liver, and kidneys. Gastrointestinal, splenic, musculoskeletal, or nodal involvement is uncommon.

Laboratory findings include either leukocytosis or leukopenia and elevated serum IgG or IgM. Cerebrospinal fluid may have abnormal protein and glucose levels. Serologies for autoimmune diseases are negative, but serologic evidence of EBV infection may be present.

The imaging findings of LYG in the lung are fairly well established.[82] In greater than 80% of cases, multiple nodules are found in a bronchovascular distribution, usually in both lungs, with a basilar predominance (Fig. 119-17). Cavitation is seen in around 30% of cases (Fig. 119-17). Nonspecific reticulonodular infiltrates, as well as solitary infiltrates or masses, are less common. Ground-glass opacities and small pulmonary nodules with a predominant peribronchovascular distribution and sparing of the periphery are rarely reported. Cases initially presenting with bilateral ground

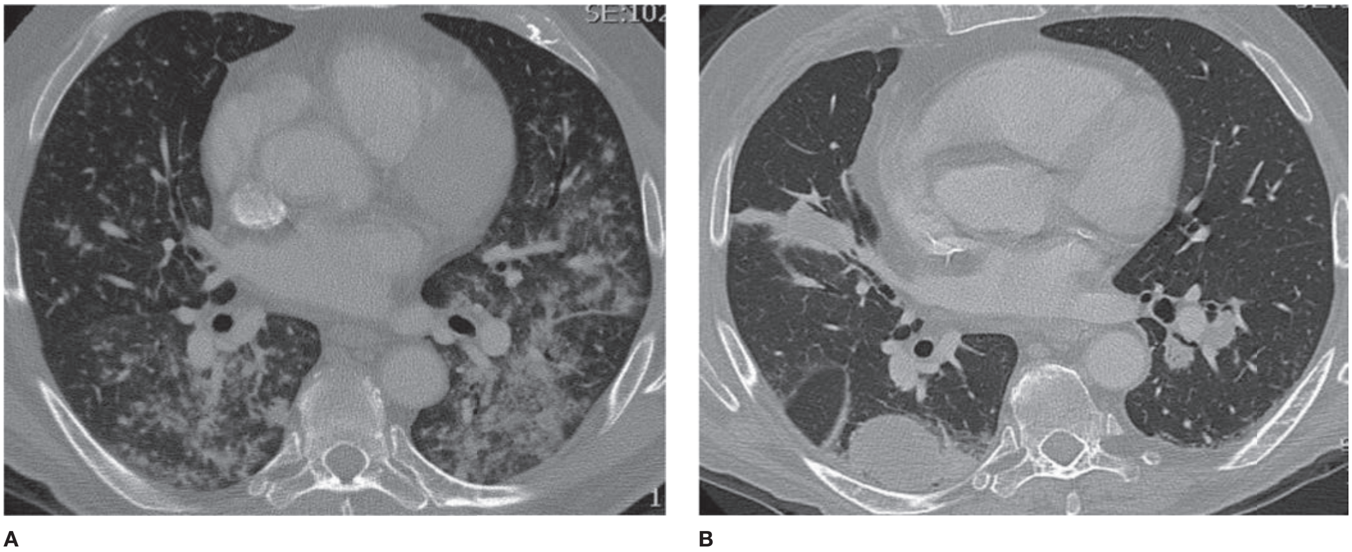

Figure 119-17 Lymphomatoid granulomatosis. **A.** CT scan shows numerous poorly defined ground glass and solid nodules throughout the lung, mainly in a peribronchovascular distribution, with areas of coalescence. **B.** CT scan from another patient demonstrating nodular mass in right lower lobe. *(continued)*

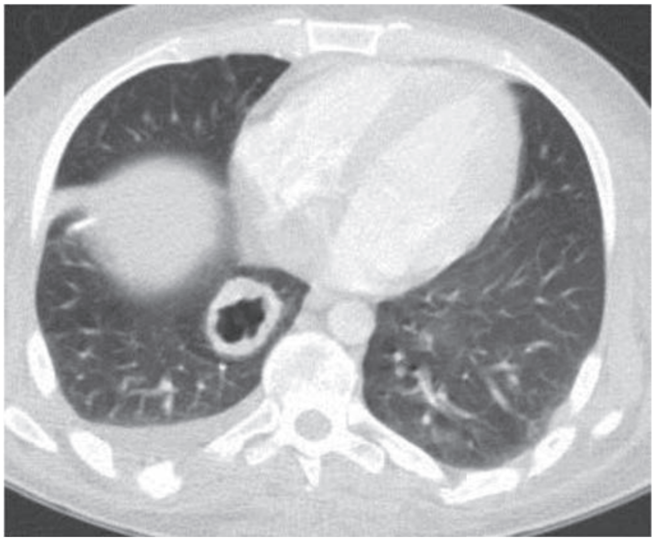

Figure 119-17 *(Continued)* **C.** Nodules are often cavitary and thick-walled.

glass opacities and respiratory failure responding in part to corticosteroids (organizing pneumonia–like manifestation), but eventually progressing to overt nodular lesions, have been observed. Pleural effusion is present in up to one-third of patients. PET is useful in documenting lesions in the lungs and in other sites. Cases with a prominent endobronchial manifestation have been reported. CT scan of the brain should always be part of the diagnostic workup. The differential diagnosis of LYG includes infections, primary pulmonary or metastatic neoplasms, cryptogenic organizing pneumonia, granulomatosis with polyangiitis, nasal-type extranodal T/NK cell lymphoma, and IgG4-related fibroinflammatory disorder.

Macroscopically the lungs and other affected organs contain yellow–white well-demarcated masses, with either solid or granular textures. Microscopically LYG is characterized by nodules containing a polymorphous lymphoid infiltrate with an angiocentric distribution (Fig. 119-18). The majority of the cells are T cells (predominantly CD4+ lymphocytes) admixed with a variable number of histiocytes, plasma cells, and immunoblasts. Central necrosis is often present to a variable extent. The larger cells are B cells (CD20+ and CD79a+), which are EBV-infected according to PCR and in situ hybridization studies (Fig. 119-19). CD30 positivity is also noted in infected monoclonal cells. EBV-positive cells vary in size and may show cytologic atypia. They may have an appearance of immunoblasts but can rarely resemble Reed-Sternberg cells with multinucleated forms. Despite the name of the disorder, well-formed granulomas are absent.

LYG is graded by comparing the proportion of EBV-positive B cells and their degree of cytologic atypia to the background population of reactive T cells. Grade 1 lesions are composed of polymorphous lymphoid infiltrate without significant atypia; necrosis may be focal or absent. Large EBV-positive lymphoid B cells are rare. Some of the cases previously included in the now obsolete classification of benign lymphocytic angiitis are likely grade 1 LYG. In grade 2 lesions, large EBV-positive cells are easily identifiable (5–50 per high-power field [HPF]), and necrosis is more common. Grade 3 lesions are characterized by a greater number of EBV-positive cells (>50 per HPF), and necrosis is common and often extensive. The large, atypical cells may occur in clusters. However, if there is a uniform population of large, atypical cells, a diagnosis of EBV-positive B-cell lymphoma is more appropriate. Given the complex histologic features of LYG and the need to identify scattered large cells in an inflammatory mass, diagnosis and accurate grading almost always requires generous biopsy samples. Immunohistochemistry is fundamental for a precise diagnosis. Clonal immunoglobulin gene rearrangements may be identified in most grade 2 and grade 3 lesions. B-cell clonality may not be detected in grade 1 lesions, most likely due to the paucity of EBV-positive cells. Clonal T cell receptor gene rearrangements are usually not present, although restricted patterns may be observed.

The natural history of LYG is variable, and clinical behavior ranges from indolent to aggressive. Histologic grade correlates with outcome. Most patients have either grade 1 or 2 disease; one-third of those with grade 1 lesions progress to grade 3/malignant lymphoma, whereas two-thirds of those with grade 2 lesions develop grade 3/malignant lymphoma. Asymptomatic patients, or those with minimal disease and grade 1 or 2 histology, may be observed. Clinically aggressive grade 2 and all grade 3 lesions are treated as DLBCL with chemotherapy plus rituximab or with stem cell transplantation. In more indolent cases, therapies targeting EBV-bearing B cells (interferon-α2β) or reactive T cells (cyclosporine) have been reported. As many as 63% of patients die, with a median overall survival of 14 months.

Intravascular Variant of DLBCL

An intravascular variant of DLBCL has been identified, characterized by the selective growth of malignant cells within the lumen of vessels, particularly capillaries;[1,2,72] it presents without adenopathy, organomegaly, or mass-forming lesions in solid organs. The vessels are filled with aggregates of large cells with coarse chromatin and a high nucleus-to-cytoplasm ratio that is clearly different from resting lymphocytes or monocytes (Fig. 119-20). Scattered extravascular atypical lymphoid cells may be detected as well. The neoplastic cells express mature B cells markers and frequently also CD5 and PD-L1; they characteristically have a defective expression of adhesion molecules.[84]

While there may be a prominent pulmonary component, the disease is never restricted to the lung and should be regarded as an aggressive, systemic lymphoma from the outset. Two major patterns of clinical presentation have been recognized: the so-called classic form (mostly present in Western countries), which is characterized by symptoms related to the main organ involved, predominantly neurologic or cutaneous, and a hemophagocytic syndrome–associated form, originally documented as an Asian variant, in which patients present with multiorgan failure, hepatosplenomegaly, and pancytopenia. B symptoms, particularly fever, are very common in both patterns of presentation. When the lungs are mainly involved, the differential diagnosis includes a thromboembolic event or an interstitial pneumonia. Pulmonary function tests document a preservation of lung volumes, along with a significant decrease of $\mathrm{DL_{CO}}$. Echocardiography usually shows an increased pulmonary artery systolic pressure. CT features include ground-glass opacities (occasionally associated with reverse halo sign), multiple centrilobular nodules, interlobular septal thickening, interstitial shadows and thickening of bronchovascular bundles, mosaic attenuation, intraparenchymal linear calcifications, and pleural effusion (Fig. 119-21). Serum LDH is markedly elevated, and hypercalcemia may be rarely observed. A random skin biopsy of normal-appearing skin and lung biopsy are often helpful in making the diagnosis.[85] Treatment is usually R-CHOP, combined with high-dose methotrexate and intrathecal chemotherapy, which is of benefit when a diagnosis is made in the early phases.[86]

Plasmacytoma

Extraosseous (extramedullary) plasmacytomas most often affect the upper respiratory tract. Primary plasmacytomas of the lung are exceedingly rare; patients are usually in their fifth and sixth decades and are asymptomatic. Cough, dyspnea, and hemoptysis have been reported. Unlike multiple myeloma, individuals may lack a serum M-protein or Bence Jones light chains in the urine. Radiographs most commonly demonstrate a midlung or hilar solitary mass, but peripheral lesion occur.[2,87]

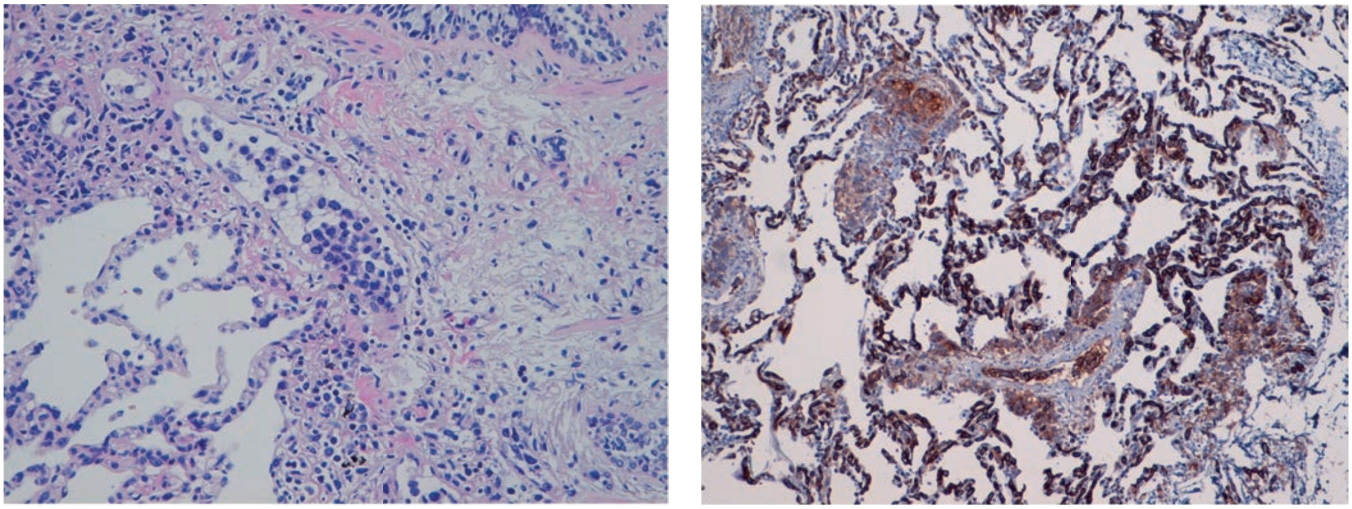

Figure 119-20 Intravascular large-B cell lymphoma of the lung. **A.** Large lymphoid cells are observed within pulmonary capillaries and small vessels (H&E, × 10). **B.** Immunohistochemistry for CD20 expressed by neoplastic cells highlights the vascular network of the alveolated lung (× 10).

Tumors range from 2.5 to 8.0 cm and most often involve a major bronchus, with occasional involvement of regional lymph nodes. Histologically, sheets of plasma cells, including binucleate forms, overrun lung parenchyma and bronchial cartilage. Fibrous bands course through the tumor, and amyloid or light chains may be associated with the neoplasm. κ and λ light chains, as well as IgG, IgA, and IgD, can be expressed immunohistochemically or produced as M-proteins by the tumor. The pathologist must discriminate between plasmacytoma and marginal zone lymphoma with plasmacytoid features, as well as inflammatory myofibroblastic tumor. Although the natural history of this rare tumor is not well delineated, surgical excision or radiation therapy may be curative, although some cases evolve into multiple myeloma. The presence or absence and amount of M-protein may mirror tumor burden, while an increase or decrease in levels may be associated with recurrence or successful treatment, respectively. An overall 5-year survival of 40% has been reported.

■ Amyloidosis

Amyloidosis related to B-cell lymphoproliferative disorders may involve the lower respiratory tract in three distinct forms: diffuse alveolar septal amyloidosis, nodular amyloidosis, and tracheobronchial amyloidosis.[1,72] Immunoglobulin light chains, typically λ light chains, represent the protein present in the fibril. Diffuse alveolar septal amyloidosis is characterized by the presence of amyloid deposits in the alveolar septa. Most cases represent pulmonary manifestations of systemic AL amyloidosis. Pleural effusion may be a manifestation of AL amyloidosis. Nodular amyloidosis is defined as one or more tumorlike amyloid deposits that involve the pulmonary parenchyma (Fig. 119-22). The process is rarely associated with systemic diseases, such as plasma cell myeloma; it is usually related to a localized lymphoproliferative process, such as MALT lymphoma, even if the process is subtle. It typically appears as solitary or multiple nodules with calcification (Fig. 119-23). Cavitation is rare; however, cysts are not infrequently observed. In tracheobronchial

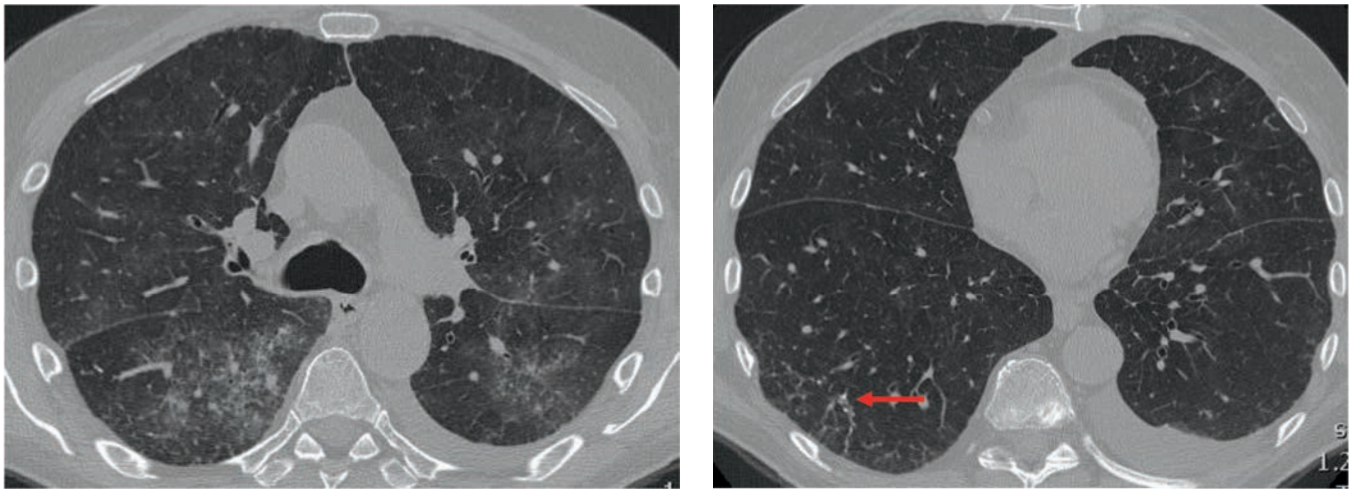

Figure 119-21 Intravascular large-B cell lymphoma of the lung. **A.** Axial CT scan shows patchy ground glass opacities associated with focal areas of septal thickening and consolidation. **B.** Scattered calcifications are present along the secondary lobular margins in the right lower lobe *(red arrow)*.

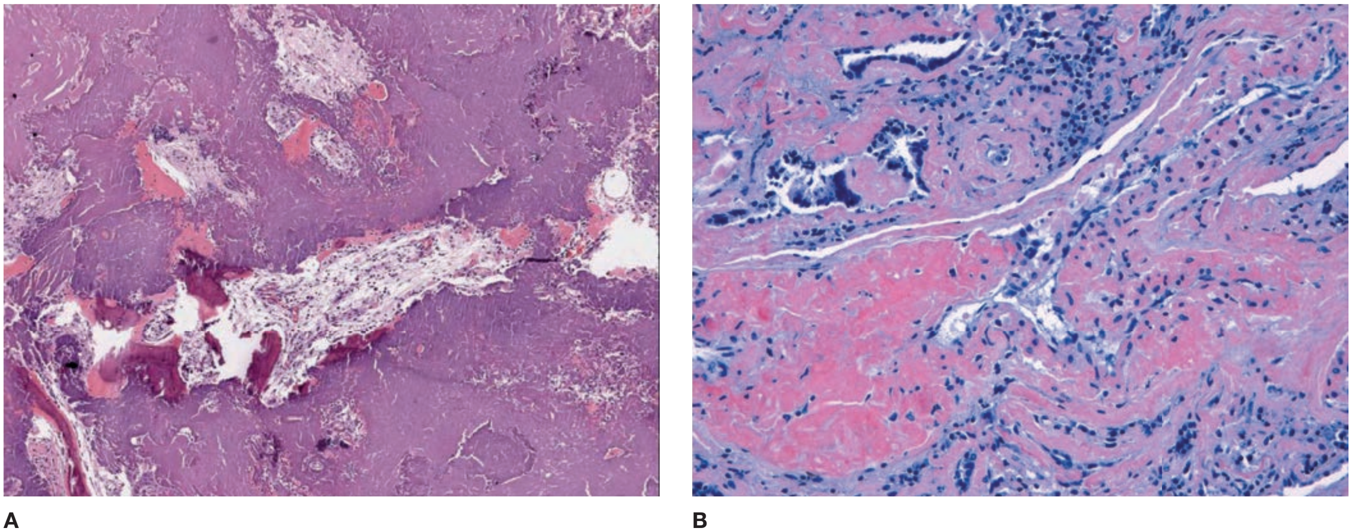

Figure 119-22 Pulmonary AL amyloid. **A.** A large deposit of amorphous, eosinophilic material entrapping a bronchiole (H&E, × 10). **B.** The Congo red–stained section shows that the amorphous material appears red (× 20).

amyloidosis, amyloid is deposited in various segments of the trachea and bronchi; the B-cell clones may be hidden and difficult to document, even using molecular tests. Bronchoscopy may document irregular whitish deposits, most often diffuse, which narrow the airway lumen. Three patterns of involvement have been described: proximal, mid-, and distal airway. Subglottic stenosis may mimic Granulomatous with Polyangiitis (GPA) or other rare forms of tracheal involvement. A daratumumab–bortezomib combination can be used in cases of diffuse lung involvement. Stenosis of large airways may be treated by bronchoscopic debulking and stent insertion.[88]

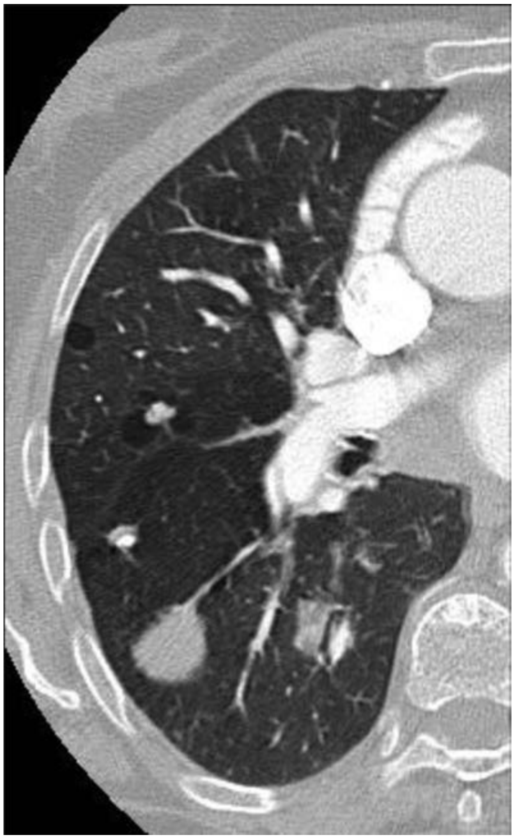

Figure 119-23 Nodular AL pulmonary amyloidosis. Axial CT showing large nodules, some partially calcified, and scattered cysts.

■ Light Chain Deposition Disease

Colombat et al. reported a very rare form of light chain deposition disease that presents as a diffuse cystic lung disorder and, in their original series, led to respiratory failure and need for lung transplantation[89] (Fig. 119-24). It was hypothesized that monoclonal light chain synthesis occurs within the lungs. This was based on the absence of disease recurrence after bilateral lung transplantation and serum-free light chain ratio normalization after the procedure.[28] Histologic examination of the explanted lungs identified diffuse, non-amyloid κ light chain deposits associated with a mild lymphoid infiltrate composed of aggregates of small CD20(+), CD5(−), CD10(−) B lymphocytes, reminiscent of BALT. A dominant B-cell clone may be identified using PCR. The deposits appear crimson red with a Masson trichrome stain and salmon pink with a sulfated Alcian blue stain; they do not stain with Congo red and do not demonstrate apple-green birefringence under polarized light. These characteristics are helpful in differentiating these deposits from those detected in amyloidosis[90] (Fig. 119-25). A very few cases manifesting with thin walled bronchiectasis have been reported.

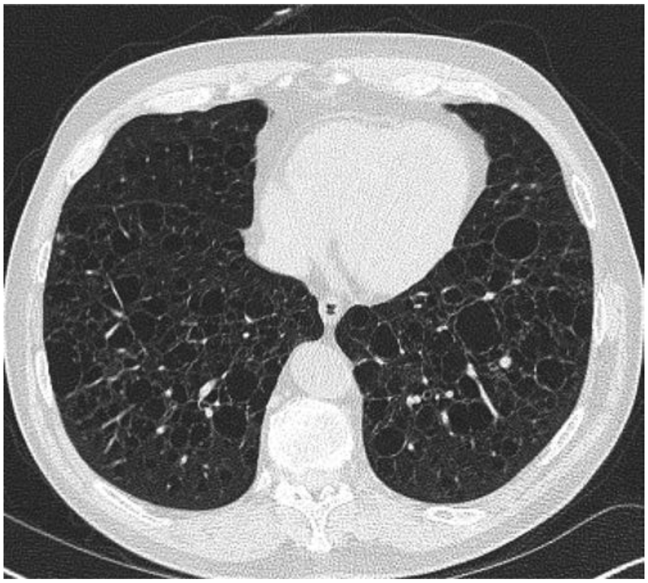

Figure 119-24 Pulmonary light chain deposition disease. HRCT shows innumerable thin-walled cysts.

■ Extranodal Natural Killer T-Cell Lymphoma (Nasal Type)

Extranodal natural killer T-cell lymphoma (ENKTCL), nasal type, is a predominantly extranodal lymphoma of NK-cell or T-cell lineage characterized by vascular damage and destruction, prominent necrosis, cytotoxic phenotype, and association with EBV. It is predominantly seen in middle-aged men from Asia, Mexico, and South America, but it has also been reported in Western countries.[1,2] It presents as tumors or destructive lesions in the nasal cavity, maxillary sinuses, or palate; it may also appear mainly localized to the lungs. Pulmonary (hemoptysis, chest pain) and systemic symptoms (fever, asthenia) are common. The first symptoms may be due to coexisting pulmonary infections (fungal, viral) or to hemophagocytic syndrome.[72] Laboratory tests may document CD4+ lymphocytopenia in peripheral blood.[72] CT scan shows nodules or masses with an important necrotic component. ENKTCL ranges from monomorphic, small/medium-sized cell lymphomas to large cell lymphomas and is characterized by frequent features of angioinvasion and angiocentrism, as well as necrosis. The neoplastic cells usually express cytoplasmic CD3, are CD2+, CD5+, CD7+CD16 +/−, and CD56+ and have an activated cytotoxic profile. By definition, all cases are associated with expression in the neoplastic cells of EBV-latent infection markers (EBERs, latent membrane protein 1, and EBNA2). Recent studies have documented consistent programmed death ligand 1 (PD-L1) expression by ENKTCL neoplastic cells, suggesting that checkpoint inhibitors may represent a therapeutic option for patients who are refractory to standard lines of chemotherapy.[91,92]

■ Peripheral T Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphoma (PTCL), not otherwise specified (NOS), constitutes a heterogeneous category of nodal and extranodal mature T-cell lymphomas that do not correspond to any of the specifically defined entities of mature T-cell lymphoma in the current WHO classification.[1,72] Excluded from this category are tumors with a T follicular helper cell phenotype, as defined by the expression of at least two (ideally, three) of the following markers: CD10, BCL6, PD1, CXCL13, CXCR5, ICOS, and SAP. PTCL, NOS nearly always presents in adults and has an aggressive clinical course. Expression in the neoplastic cells of EBV-latent infection markers may be documented in a minority of cases. Natalizumab, an anti-integrin alpha-4 monoclonal antibody used for treatment of multiple sclerosis, has been reported to be associated with PTLC.

Rarely, PTLC, NOS may present as a localized lung lesion. Patients usually present with cough, dyspnea, chest pain, fever, and hemoptysis. Not infrequently a superimposed pulmonary infection (bacterial, fungal or even viral) may be the first manifestation of the underlying lymphoma. Laboratory tests may document lymphopenia and eosinophilia. Serum autoantibodies (such as proteinase-3 antineutrophil cytoplasmic antibodies) may be detected. Hemophagocytic syndrome is a rare but ominous complication.

CT features include alveolar consolidation and large nodules with or without cavitation. Areas of ground glass and/or crazy paving are rarely reported. These features may be explained in part by the presence of organizing pneumonia around the lymphoid neoplastic infiltrates. Pleural effusion as first manifestation is very rare.

The cytologic spectrum is extremely broad, ranging from polymorphous to monomorphic. Most cases consist of numerous small/medium-sized and/or large cells with irregular, pleomorphic, hyperchromatic, or vesicular folded nuclei, prominent nucleoli, and many mitotic figures. Clear cells and Reed-Sternberg-like cells also can be seen. Rare cases have a predominance of small lymphoid cells with atypical, irregular nuclei. Neoplastic cells express T-cell markers, such as CD3 and CD2 with a CD4 or CD8 phenotype, with frequent downregulation of CD5 and CD7. A CD4/CD8 double-positivity or double-negativity is sometimes seen. CD15 may be positive and may be coexpressed with CD30 in rare instances. CD15 expression is associated with an adverse prognosis. The neoplastic cells infiltrate the lung parenchyma with a perivascular/perilymphatic distribution. Infection of neoplastic cells by EBV is reported in a small number of cases. The background consists of a mixed inflammatory infiltrate (small lymphocytes, frequent eosinophils, plasma cells, and a variable number of epithelioid histiocytes, with loosely formed granulomas, mainly in the lymphoepithelioid or "Lennert" variant). Organizing pneumonia features may be prominent around the neoplastic infiltrate. In areas of necrosis a superimposed infection may be documented. Diagnosis requires a generous biopsy sample, and if less invasive approaches fail, surgical lung biopsy is mandatory.

Anthracycline-based combination chemotherapy remains the most frequently used frontline strategy. However, prospective studies have shown that consolidation with high-dose chemotherapy and autologous stem cell transplantation results in a better progression-free survival.[93,94]

■ Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma (ALCL) is a rare non-Hodgkin T/NK cell lymphoma. The WHO 2017 Classification defined ALCL as a CD30+T/NK cell neoplasm that is further subdivided in two distinct entities by ALK protein expression (ALK-positive ALCL and ALK-negative ALCL). A chromosomal translocation involving the ALK gene (2p23) is present.[1,95] The lung is a common site of secondary involvement by systemic T cell-ALCL, but rare cases of primary pulmonary ALCL of T or NK cell type have also been reported.

Lung parenchymal masses or single nodules are the features observed on CT scan. Rarely, ALCL may appears as a large airways endoluminal mass. Morphologically it is characterized by large anaplastic, pleomorphic cells with "horseshoe-shaped" nuclei and abundant cytoplasm. In some cases, the nuclear indentation is in the plane of view, such that the nucleus appears as an "O" (donut cells). The majority of these cases are positive for a pan–T cell marker, such as CD2, CD3, or betaF1, although some may be negative for these antigens (null cell phenotype) or negative for leukocyte common antigen. Neoplastic cells express CD30.

Because ALK is essential for the proliferation and survival of ALK-positive ALCL cells, it provides a unique therapeutic target. Promising clinical results have been achieved in small case series of ALK+ ALCL with small molecule inhibitors of ALK kinase. CD30-targeting with antibody/drug conjugates and brentuximab vedotin also has been utilized. The clinical outcome of ALK-negative ALCL with conventional therapy is poorer. However, approximately 30% of cases harbor DUSP22 rearrangements, and this subtype has a favorable prognosis similar to that seen in ALK-positive ALCL.[95]

■ Hodgkin Lymphoma

Classic Hodgkin lymphoma (HL) rarely can appear as a primary lung disorder.[2,96–98] This occurs more frequently in females, and patients are usually older than those with primary nodal disease. Cases of primary pulmonary HL occurring in patients treated with methotrexate for autoimmune diseases have been reported.[99] Reticulonodular infiltrates, single or multiple nodules (frequently cavitary), and alveolar consolidation are the main radiographic manifestations. Patients are usually symptomatic with cough, fever, weight loss, night sweat, dyspnea, fatigue, anorexia, chest pain, and/or pruritus. The "nonclassic" or lymphocytic-predominance subtype has not yet been reported a primary lung tumor.

Diagnosis of the "classic" HL requires the identification of Reed–Sternberg cells or its variants. These cells are CD30+ in nearly all cases and CD15+ in most. The B-cell nature of the Hodgkin-Reed Sternberg cells is demonstrable by the expression of the B cell–specific activator protein PAX-5. The prevalence of EBV in HL cells varies according to the histologic subtype and epidemiologic factors. EBV-infected neoplastic cells express LMP1 and EBNA1 without EBNA2, a pattern characteristic of type II EBV latency. In the lung the mixed inflammatory milieu of HL may overlap substantially with reactive conditions.

Central necrosis, granulomatous inflammation, and vascular and bronchial infiltration by the polymorphous infiltrate are commonly seen. The morphologic differential diagnosis includes inflammatory and malignant processes, infections, GPA, sarcoidosis, poorly differentiated carcinomas, inflammatory solitary fibrous tumor, inflammatory myofibroblastic tumor, LYG, and a variety of non-Hodgkin lymphomas.

The prognosis for patients with primary pulmonary HL is variable. Relapses occur in the lung and elsewhere and appear associated with multiple lobe involvement, pleural invasion, cavitation, and presence of B symptoms. Treatment is with the ABVD regimen. However, in patients with methotrexate-related HL, use of bleomycin can result in an increased lung toxicity, and an alternative regimen consisting of brentuximab vedotin, in combination with doxorubicin, vinblastine, and dacarbazine, has been adopted.[100] PD-L1 antibody therapy is beneficial in relapsed/refractory HL.[101,102]

■ Pleural Lymphomas

Two major types of lymphoma involve the pleura as primary neoplasms: primary effusion lymphoma (PEL) in the setting of HIV infection, and pyothorax-associated lymphomas (PAL), with a strong Epstein-Barr virus (EBV) or pyothorax association.[1,2] A rare form of microscopically proliferation of large B cells found incidentally with fibrin in pleural or other confined anatomical spaces has been recently reported and called fibrin-associated diffuse large B cell lymphoma.[1,2]

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is a peculiar form of malignant lymphoproliferative disorder. According to the WHO classification,[1,2] classic PELs present as serous effusions with or without mass lesions over the entire course of the disease. Extracavitary PELs are less common, representing approximately one-third of the cases.[2,103] PEL occurs in HIV-infected patients, but also rarely in the setting of transplantation and in elderly patients. Neoplastic cells exhibit a range of appearances, from large immunoblastic to anaplastic, and their nuclei are positive for HHV-8 latent proteins. Most cases (usually those manifesting in HIV patients) are coinfected with EBV. The malignant cells express CD45 and CD30, but pan–B cell markers are not expressed. However, terminal B-cell differentiation markers, such as MUM1, CD38, and CD138, are expressed. Eventually, aberrant expression of T-cell markers (CD2, CD3, CD4, and CD5) may be detected.[104] Cytologic analysis of fluid, along with PCR to identify HHV-8, is usually diagnostic. Treatment options for PEL include cyclophosphamide, doxorubicin, vincristine, and prednisone-based chemotherapy regimens alone or in combination with immunomodulatory agents (e.g., lenalidomide) and proteasome inhibitors (e.g., bortezomib).[105] Several case reports have shown prolonged complete remission with brentuximab vedotin.[104] Highly active antiretroviral therapy should be initiated or continued in patients with associated HIV infection. Prognosis, however, remains grim.

Pyothorax-Associated Lymphoma

Pyothorax-associated lymphoma (PAL) is a lymphoid neoplasm that develops in the pleural cavities of immunocompetent patients with chronic suppurative pleuritis; it is linked with EBV.[1,2,72,106,107] Most cases arise decades after artificial pneumothorax for treatment of tuberculosis or tuberculous pleuritis. Approximately 2% of individuals with chronic pyothorax develop PAL. Patients, more often males, are usually in their sixth to eighth decades of life and usually present with chest pain, back pain, shoulder pain, and dyspnea. Radiographic studies demonstrate an intense ^{18}F fluorodeoxyglucose PET–positive visceral or parietal pleural mass that may invade the chest wall, lung, pericardium, or diaphragm in the setting of pleural fibrosis and calcification.[108,109]

Biopsy and resection specimens show masses composed of sheets of large atypical lymphoid cells with prominent nucleoli and basophilic cytoplasm. Mitotic figures and apoptotic bodies, as well as necrosis, abound. Immunohistochemical studies distinguish this high-grade lymphoma from PEL. Typically, lymphoma cells associated with PAL stain for B-cell antigens CD20 and CD79a; plasma cell markers CD38 and CD138; and, on occasion, a T-cell marker such as CD2, CD3, CD4, or CD7. Immunohistochemistry is positive for EBV, whereas KSHV/HHV8 is absent.

Treatment options include chemotherapy (e.g., CHOP), rituximab, and/or radiotherapy. Combination chemotherapy and radiotherapy may induce a complete response and prolong survival, with overall 5-year survival rates of 20%. Those who demonstrate a complete response to chemotherapy and/or radiotherapy achieve a more prolonged survival, with 5-year survival rates approaching 50%. Pleuropneumonectomy has been advocated for selected patients.[110]

SECONDARY LUNG INVOLVEMENT FROM EXTRATHORACIC LYMPHOMA

Secondary lung involvement due to nodal and extranodal lymphomas is significantly more common than primary pulmonary lymphoma. Lung and pleural involvement with common nodal and disseminated lymphomas surpasses 50% during life and at autopsy.[111] Clinical and radiologic features may mimic an infectious process.

Morphology does not usually allow for distinction between primary and secondary lung disease. For example, pulmonary involvement with nodal marginal zone lymphoma is indistinguishable from primary pulmonary extranodal B-cell lymphoma of MALT. Thus, clinical history and review of previous diagnostic material are necessary for proper diagnosis. Secondary lymphomas involving the lung can also transform to more aggressive histology with increased numbers of large cells. This phenomenon is not infrequently seen in samples from patients with chronic lymphocytic leukemia/small lymphocytic lymphoma.

Particular systemic lymphoproliferative disorders that may present with significant lung pathology warrant additional discussion. Mycosis fungoides may involve the lung after dissemination of cutaneous disease or as part of Sézary syndrome. Indeed, the lung is the second most common extracutaneous site after lymph nodes. Clinical and radiographic features often mimic pneumonia, or even acute respiratory distress syndrome, with nodular and diffuse disease. Tissue samples demonstrate air space and interstitial infiltrates along lymphatic routes in addition to occasional granulomas.

The lungs are also frequently involved with angioimmunoblastic T-cell lymphoma.[1,111] Neoplastic cells have a T follicular helper (TFH) cell gene expression signature and express many of the TFH cell-associated markers, such as CD10, CXCL13, BCL6, ICOS, CXCR5, SAP, MAF (also called c-MAF), and (in most cases) CD200. Cytologically, the neoplastic T cells are small- to medium-sized lymphocytes, with clear to pale cytoplasm, distinct cell membranes, and minimal cytologic atypia. Patients exhibit immunodeficiency secondary to the neoplastic process, and expansion of EBV-positive B cells may be observed in the majority of patients. This aggressive disease in the lung can be mistaken for interstitial lung disease or infectious pneumonia.

Chronic lymphocytic leukemias (B-cell type) can appear as a diffuse symptomatic lung disease mimicking nonneoplastic forms of interstitial lung disease or chronic bronchiolitis.[112] BAL with flow cytometry and/or transbronchial biopsy are usually diagnostic.[112] T-cell large granular lymphocytic leukemia may appear as a cystic lung disease.[113]

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

Posttransplant lymphoproliferative disorder (PTLD) occurs after solid organ transplantation or hematopoietic stem cell transplantation.[113,114] Among adults, patients receiving renal allografts have the lowest frequency of PTLD (generally <1%); those with hepatic and cardiac allografts have an intermediate risk (approximately 1%–5%); and those receiving heart–lung, lung, or intestinal allografts have the highest frequency (≥5%). In general, allogeneic hematopoietic stem cell recipients have a low risk of PTLD (~1%–2%). These disorders constitute a spectrum of lymphoproliferative entities, including early lesions (which are also defined as "mononucleosis-like" and are always EBV-positive), polymorphic PTLDs (which are characterized by a mixture of B lymphocytes with infiltrating T lymphocytes, without necrosis), and a group of monomorphic PTLDs (which includes all non-Hodgkin lymphoma histologies).[2,111,115] EBV-associated lesions with histopathologic features of LYG also have been reported. Other rare monomorphic subtypes of PTLD are multiple myeloma, plasmacytoma, Hodgkin lymphoma, and EBV-negative PTLD.[114]

Lymphoid proliferations are related to a T-cell dysfunction, which results from the administration of immunosuppressive agent and, in virtually almost all cases, the presence of EBV.[116] The interval between transplantation and the onset of PTLD varies widely (from 2 to 128 months); it usually manifests 2 to 6 months after lung transplant.[114,115,117,118]

The majority of cases of pulmonary PTLD occur in lung transplant recipients. Individuals may be asymptomatic or present with constitutional or respiratory symptoms. CT scan demonstrates solitary or multiple nodules or masses, sometimes with surrounding ground glass ("halo sign"); regional lymphadenopathy also may be present. Endobronchial lesions as a manifestation of PTLD have been reported.[119] Treatment strategies consist of response-adapted risk-stratified methods using immunosuppression reduction (as permitted), immunotherapy (rituximab in CD20+ lesions), and chemotherapy. Chemotherapy is reserved for CD20− lymphomas and for cases refractory to the above measures but is often poorly tolerated in immunocompromised transplant recipients.[120,121] The combination of brentuximab vedotin given concurrently with rituximab is a promising approach.[122]

CHAPTER 120

Pulmonary Clearance of Infectious Agents

Theodore J. Standiford
Gary B. Huffnagle

INTRODUCTION

The primary function of the lungs is the exchange of gases at a rate required to support tissue metabolism. During gas exchange, the lung is continuously exposed to a varied burden of foreign substances, including infectious agents. In addition, microbes immigrate into the lower respiratory tract via subclinical microaspiration of oropharyngeal microbiota.[1,2] The lung has the difficult task of defending itself against this potentially hostile environment while maintaining the alveolar architecture required for adequate gas exchange. This group of nonrespiratory antimicrobial functions has been collectively termed *pulmonary host defenses*.[3]

MECHANICAL DEFENSES

Mechanical defenses of the respiratory system include those in the nasopharyngeal airway as well as those in the conducting airways.

Nasopharyngeal Airways

Nasal hairs remove most particulates larger than 10 μm. Brisk airflow and rapid changes in direction of the airstream within the nose promote inertial deposition of large particulates, which are cleared primarily by swallowing, sneezing, or coughing. Mucociliary clearance participates in the removal of particulates from the nasopharynx. Ciliated mucosa is present on the nasal septum and turbinates; mucociliary action sweeps mucus toward the posterior pharynx, where secretions are either swallowed or expelled from the throat.[4–6]

Conducting Airways

Important functional aspects of the conducting airway defense mechanisms include the mucociliary escalator and airway secretions, as discussed below.

Mucociliary Escalator

Most particulates larger than 2 μm in diameter affect the conducting airways of the lower respiratory tract. Mucociliary clearance and coughing are the principal means of mechanical defense.[5,7] The mucosa of the conducting airways is lined with mucus secreted by goblet cells, bronchial glands, and club cells (previously termed Clara cells). The mucous blanket is composed of two distinct layers: a watery periciliary layer, which provides lubrication for ciliary movement, and an upper more viscous layer that is just penetrated by the ciliary tip.[4,6–9] Mucus is propelled cephalad within the respiratory tract by the terminally differentiated pseudostratified ciliated epithelium that lines the conducting airways. Each ciliated cell has approximately 200 cilia, which are approximately 5 to 6 μm in length and have a beat frequency of 12 to 14 beats per second. Beat frequency is regulated by both environmental factors and pharmacologic agents. Particulates can be cleared from the trachea and distal airways within minutes to hours.

Airway Secretions

Secretory cells of the airway epithelium, including serous, club, and goblet cells, secrete a broad array of antimicrobial molecules.[10–13] Mucus is comprised of a complex mix of mucin glycoproteins, diverse antimicrobial peptides, and metabolites. Mucus functions to ensnare microbes for removal and protects the respiratory epithelium from microbial invasion. MUC5B and MUC5AC are the predominant mucins present in mucus, and MUC5B in particular is essential for effective mucociliary clearance.[14] Mucins have also been shown to display antimicrobial, antiprotease, and antioxidant properties.

Lysozyme is secreted in abundant quantities in human airways (10–20 mg per day). This enzyme catalyzes the hydrolysis of peptidoglycan constituents of the cell walls of most bacteria and some fungi. Airway secretions contain both serum-derived antiproteases (α1-antitrypsin, α_2-chymotrypsin, and α_2-macroglobulin) and airway epithelial cell–derived antiproteases (secretory leukocyte proteinase inhibitor [SLPI] and elafin).[8] Iron is essential for survival of many microbes.[15] Iron is sequestered in cells or firmly complexes to transport proteins. Microbes compete for this iron with their own transport proteins, known as siderophores. Lactoferrin, transferrin, and lipocalin 2 are host-derived molecules that effectively complex free iron in mucosal secretions, limiting iron required for bacterial growth.[16–18] Lactoferrin also exerts direct antimicrobial effects by disrupting microbial plasma membranes and has immunomodulatory properties on innate and adaptive immune cells.[18]

Airway secretions and alveolar lining fluid also contain the small cationic antimicrobial peptides β-defensin and cathelicidin.[8,19–22] These proteins exert broad antimicrobial activity against bacteria, fungi, and viruses through hydrostatic interactions with cell membranes resulting in cell rupture.[19,23] Cathelicidins also exert immunomodulatory properties that augment local antimicrobial responses, including stimulation of inflammatory cytokine production and induction of neutrophil extracellular trap (NET) release from neutrophils.[24] Different classes of antimicrobial molecules can function in a synergistic fashion to markedly enhance microbial killing.[25] For instance, sub-MIC concentrations of lysozyme and lactoferrin can substantially enhance the bacterial killing activity of β-defensins and cathelicidins. The respiratory epithelium also has the ability to generate reactive oxygen species at bactericidal concentrations. Hydrogen peroxide is produced in the airway via the dual NADH oxidase/peroxidase (Duox) system, which is induced during infection.[9,26] The bactericidal activity of H_2O_2 is greatly enhanced in the presence of lactoperoxidases produced in abundance by the airway epithelium.

LUNG INNATE IMMUNITY

Host immune mucosal defenses against invading microbial pathogens consist of two distinct but integrated components: innate immunity and adaptive immunity. Innate immune recognition occurs via germline-encoded receptors that recognize conserved molecular features common to multiple microorganisms (Fig. 120-1).

Innate Immune Recognition

Microbial recognition is complex because microbes display molecular heterogeneity and have high mutation rates. The innate immune system detects a broad spectrum of pathogens using a repertoire

Figure 120-1 Pathogen recognition receptors: TLRs, NLRs, C-type lectin receptors, and RIG-I system for detection of extracellular and intracellular PAMPs. TLRs 1, 2, and 4–6, and C-type lectin receptor are extracellular; TLRs 3, 7/8, and 9 detect PAMPs within endosomes; NLRs and RIG-I detect intracellular PAMPs. All are signaling receptors. ds, double stranded; HSP, microbe-derived heat shock protein; LPS, lipopolysaccharide; LTA, lipoteichoic acid; ss, single stranded.

of invariant extracellular and intracellular receptors that recognize highly conserved microbial molecules including combinations of sugars, proteins, lipids, and distinct nucleic acid motifs. The receptors that recognize these molecular patterns are termed pathogen recognition receptors (PRRs). The microbial ligands recognized by PRRs are referred to as pathogen-associated molecular patterns (PAMPs). PAMPs share certain features. Specifically, PAMPs are invariant structures shared by classes of pathogens, are produced only by microbes, and are essential for microbial pathogenicity or microbial survival.[27] PRRs also recognize certain host-derived signals released in the setting of cellular stress or injury, referred to as danger-associated molecular patterns or DAMPs.[28,29]

PRRs can be divided into two general classes: endocytic and signaling receptors. Macrophage scavenger receptors (MSR), including SR-AI/II, MARCO, and CD36 have broad specificity for varied polyanionic molecules, including environmental particles, apoptotic cells, and microbial components.[30,31] Microbial ligands for scavenger receptors include double-stranded RNA, LPS, and lipoteichoic acid, and these scavenger receptors mediate binding and internalization of nonopsonized bacteria such as *Escherichia coli* and *Staphylococcus aureus* and some viruses.[32] While not considered classic signaling receptors, scavenger receptors can stimulate respiratory burst but generally not inflammatory cytokine production.[33] Signaling PRRs induce expression of inflammatory cytokines, chemokines, and other innate effectors molecules following binding of PAMPs. Signaling PRRs include Toll-like receptors (TLRs), nucleotide binding oligomerization domain (NOD)-like receptors, the RNA helicase retinoic acid–inducible gene I (RIG-I) system, and C-type lectin receptors.

Toll-like receptors are critical elements of innate immune recognition.[29,34–37] Ten TLRs have been described in humans and are expressed by both professional immune cells (macrophages, dendritic cells [DCs], mast cells, neutrophils, eosinophils, innate lymphoid cells [ILCs]) and lung structural cells (epithelial cells, fibroblasts, and endothelial cells).[38–42] Pattern recognition receptors (PRRs) differ from one another in ligand specificity, expression patterns, and the genes they induce. TLR1, TLR2, TLR4, TLR5, and TLR6 are expressed on the cell surface, whereas TLR3, TLR7, TLR8, and TLR9 are intracellular, primarily localized to the endosomal compartment. Several TLRs exist in both transmembrane and soluble forms serving as sinks to bind PAMPs and DAMPs. TLR2 recognizes a wide range of microbial constituents expressed primarily by Gram-positive bacteria, mycobacteria, fungi, and certain viruses such as influenza.[43–50] These PAMPs include lipoproteins, peptidoglycan, lipoteichoic acid, lipoarabinomannan, hemagglutinin, and zymosan.[51] TLR2 also forms heterodimers with other TLRs such as TLR1 and TLR6, substantially increasing the repertoire of ligands recognized by TLR2. TLR3 recognizes double-stranded RNA (dsRNA) expressed by most viruses during replication, including influenza and coronavirus.[52,53] TLR4 is the primary receptor for LPS recognition and is required for clearance of many Gram-negative bacteria, including *E. coli*, *H. influenzae*, and *K. pneumoniae*.[54,55] This TLR is also speculated to interact with the spike protein of SARS-CoV-2.[56] In addition to PAMPs, TLR4 also recognizes endogenous ligands released from activated or stressed cells, such as high-mobility group box 1 (HMGB1), heat-shock proteins, and the S100 proteins (calprotectins), as well as matrix components, surfactant proteins, and β-defensins.[28] TLR5 is activated by flagellin, the principal component of bacterial flagella.[57] TLR7 and TLR8 recognize single-stranded RNA (ssRNA) from viruses such as human immunodeficiency virus and influenza A virus (IAV).[58] TLR9 is activated by unmethylated CpG motifs present in bacterial, mycobacterial, and fungal DNA but not mammalian DNA.[59,60] This TLR mediates DC activation that is required for innate and adaptive responses to bacteria (*S. pneumoniae*, *K. pneumoniae*, *L. pneumophila*) and fungi (*Candida albicans*, *Cryptococcus neoformans*).[60–62] Most TLRs require the adaptor molecule MyD88 for downstream signaling, whereas TLR3 utilizes the adaptor TRIF. Several TLRs, including TLR2 and TLR4, can signal through both MyD88- and TRIF-dependent pathways, with the MyD88 pathway serving as the dominant pathway in innate mucosal antimicrobial responses to bacterial challenge.[63–65]

Another class of signaling PRRs is the NOD-like receptors (NLRs).[66] NLRs exist within the cytosol and function to recognize intracellular PAMPs or DAMPs. NLRs activate the inflammasome, an intracellular multimeric protein complex that regulates the maturation and release of proinflammatory cytokines of the IL-1 family (IL-1β, IL-18). NLRs are activated by a diverse group of PAMPs, including the bacterial cell wall components peptidoglycan and muramyl dipeptide (MDP), bacterial flagellin, and several bacterial toxins.[67,68] NLRs and their adaptor molecules contribute to protective immunity against diverse respiratory pathogens, including extracellular (*S. aureus*, *S. pneumoniae*, *K. pneumoniae*) and intracellular bacteria (*L. pneumophila*, *Chlamydia pneumoniae*), and viruses such as RSV.[69–71] NLRs can act cooperatively with TLRs to amplify innate responses. For instance, TLR5 and the NLR IPAF/Nlrc4 function cooperatively to optimally eradicate flagellated bacteria such as *P. aeruginosa* and *L. pneumophila* from the alveolus.[72]

RNA helicase retinoic acid–inducible gene I (RIG-I) is a complimentary cytosolic system to sense and respond to pathogen-specific 5′-di- or -triphosphate RNA.[58,73,74] RIG-I and family member MDA5 are expressed most prominently by myeloid (conventional) DCs and respiratory epithelial cells, and are major drivers of virus-induced type 1 interferon production. During influenza infection, both TLR7 and RIG-1 are required for maximal antiviral IFN-α/β responses, with TLR7 mediating IFN production from plasmacytoid DCs, and RIG-I necessary for myeloid DC IFN responses.[75] RIG-I can also sense bacterial mRNA that translocates to the cytosol, although the requirement of this PRR in control of bacterial infection has not been defined.

C-type lectin family are signal-transducing type I and II transmembrane proteins that are expressed mainly in DCs, macrophages, and neutrophils.[76–79] This family contains one or more carbohydrate recognition domains that allow for recognition of glucans present in most classes of human pathogens, including bacteria, fungi, and viruses. The family of C-type lectin receptors includes the mannose receptor, DC-specific ICAM3-grabbing non-integrin (DC-SIGN), macrophage-inducible C-type lectin (Mincle), and the Dectin receptors. Like TLRs, C-type lectin receptors can exist in both soluble and transmembrane forms. The mannose receptor (CD206) interacts with Gram-positive and Gram-negative bacteria and fungal pathogens and mediates phagocytosis. DC-specific intracellular adhesion molecule 3–grabbing non-integrin (DC-Sign) is a type II membrane C-type lectin expressed predominantly by DCs and resident alveolar macrophages (AMs).[80] This PRR recognizes galactomannans of diverse pathogens, including bacteria, mycobacteria, fungi and viruses.[81] Mincle is expressed by myeloid cells and senses glycolipids primarily from mycobacterium, but also certain fungal and bacterial pathogens.[79] Dectin-1 recognizes β-glucans, whereas dectin-2 is activated by α-mannans. Both β-glucans and α-mannans are major cell wall components of fungi, including *Pneumocystis jiroveci*, *Aspergillus fumigatus*, and *C. albicans*.[77,78,82,83] Dectins are key receptors for antifungal host defense. Activation of C-type lectin receptors can induce reactive oxygen species, production of cytokines and chemokines (CXCL1, CXCL8, IL-23, IL-17A, and IL-22), and influx of PMNs required for effective innate antimicrobial responses.

■ Resident Lung Innate Immune Cells

Cells resident in the lung that are important in immune defense include macrophages, lymphoid cells, and alveolar epithelial cells.

Alveolar Macrophages

Resident alveolar macrophages (AMs) are a heterogeneous population of phagocytes that constitute the first line of defense against microbes that reach the alveolus.[50,84,85] These cells are embryonically derived and self-renewing from precursors present within the lung. Alveolar macrophages are also derived from circulating monocytes during inflammatory conditions. Alveolar macrophages have a life span of months to years. Other resident macrophage populations exist in the lung, including within the airway, interstitium, pleura, and intravascular space. These various macrophage populations are phenotypically distinct for one another and from macrophages that reside in the alveolar space. Under basal conditions, resident AMs produce low levels of inflammatory cytokines, maintain high phagocytic capability, and generally function to suppress inflammation and adaptive immunity within the lung.

The antimicrobial function of AM is dependent on four essential attributes. Macrophages recognize host- and microbe-derived signals, migrate in response to stimuli, secrete mediators, and ingest and kill invading microbial pathogens.[50] Macrophages recognize signals in their microenvironment via PRRs and surface receptors capable of binding specific ligands, including complement proteins, immunoglobulins, cytokines, apoptotic cells, PAMPS, and DAMPS (Fig. 120-2). Ligation of TLRs induces transcriptional activation of inflammatory cytokines (TNF-α, IL-6, and the IL-1 family members IL-1α/β and IL-36 α/γ), chemokines, and signals that regulate the differentiation and activation of lymphocytes, such as IL-10, IL-12, and type 1 IFNs. Early response cytokines produced by AMs network with structural cells of the alveolar-capillary membrane, including alveolar epithelial cells (AECs).[86–89] Alveolar macrophages also communicate with AECs via the release of membrane-encapsulated microvesicles containing bioactive cargo and by direct cell–cell calcium-dependent signaling through connexin 43–containing gap junction proteins.[90,91] Compared with monocytes and macrophages in other tissue compartments, AMs preferentially produce 5-lipoxygenase rather than cyclooxygenase products, including LTB_4 and LTC_4, resulting in robust PMN recruitment and activation.[92] During their quiescent state, resident AMs present antigen poorly. However, PRR ligation results in upregulation of costimulatory molecules (CD80, CD86) and transform these cells into capable antigen-presenting cells.[50]

Alveolar macrophages migrate within the alveolar space in response to both endogenous signals and mechanical stimuli.

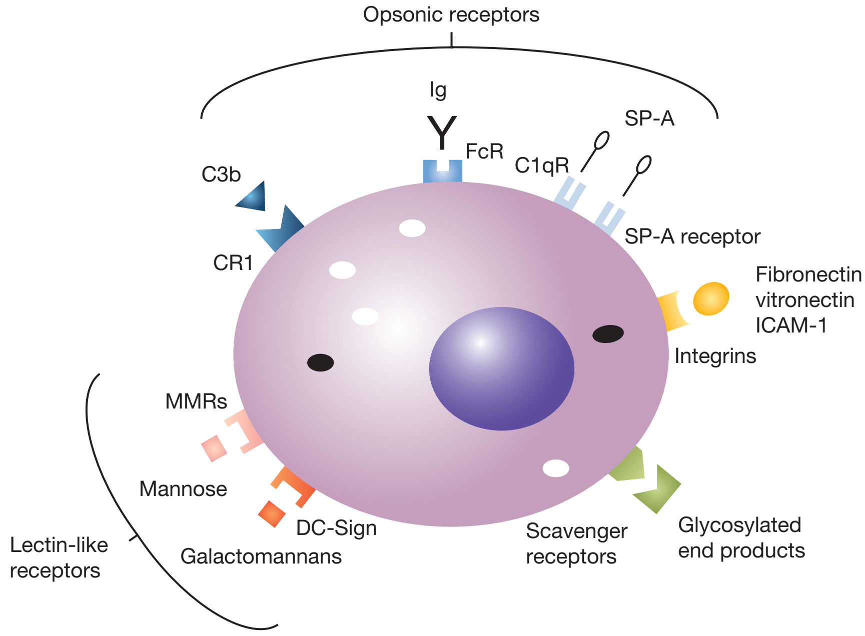

Figure 120-2 Cell surface receptors expressed by resident AMs mediating adherence, movement, and pathogen internalization. Opsonic receptors mediate attachment and phagocytosis of pathogens opsonized with C3b, immunoglobulin, or SP-A. C-type lectin receptors and scavenger receptors mediate attachment and internalization of nonopsonized microbes expressing specific carbohydrate moieties. Integrins mediate alveolar macrophage binding to and migration along matrix components or alveolar epithelium.

The movement of these cells in response to bacteria is dependent upon chemotactic signals, including surfactant proteins (SP-A), chemokines (CCL2), and adhesion molecule (ICAM-1) expression by AECs.[93–95] Mechanical stretch of the alveolus can also stimulate directed movement of AMs.

Alveolar macrophages are highly phagocytic cells. The opsonization of microbes by the complement component C3b or immunoglobulin binding greatly facilitates phagocytosis. Macrophages express two distinct receptors for C3b. Complement receptor 1 (CR1) preferentially binds C3b, whereas the complement receptor 3 (CR3, Mo-1, MAC-1, CD11b/18) is a member of the β_2 integrin family required for cell–cell and cell–substrate adhesion. Three Fcγ receptors recognize the Fc domain of immunoglobulin G (IgG). All FcRs function as signal-transducing molecules. FcγRI, FcγRII, and FcγRIII trigger both phagocytosis and cytolytic responses, with FcγRII and FcγRIII the most indispensable.

Alveolar macrophage also expresses multiple cell surface receptors that promote binding and internalization of nonopsonized particulates, including microbes. The macrophage mannose receptor binds mannose and mediates phagocytosis of yeasts, zymosan particles, and *P. jiroveci* (Fig. 120-2). Scavenger receptors bind apoptotic cells and acellular debris, and they serve as a major mechanism to internalize nonopsonized Gram-positive and Gram-negative bacteria, such as *S. aureus*, *S. pneumoniae*, and *E. coli*.[30,31] SP-A-opsonized microorganisms binds to specific high-affinity receptors and C1q receptors, triggering internalization and increased cell-surface expression of macrophage Fc receptors, mannose receptors, and scavenger receptors. Binding of microbes to DC-SIGN can signal an IL-10–predominant anti-inflammatory response, thus subverting from a killer to a permissive phenotype in responding cells.

Phagocytosis requires sequential, circumferential interaction of phagocyte surface receptors with complementary ligands on the surface of the particle. The ingested microbe is initially contained within a phagosome that subsequently fuses with lysosomes to form phagolysosomes. TLR stimulation is linked to phagosomal maturation. The killing capacity of resting resident AM is low, and these cells require activation signals from the microenvironment for intracellular killing to occur. Activation stimuli include microbial products, inflammatory cytokines, and plasma proteins. Most notable is IFN-γ, the primary activator of macrophage antimicrobial effector responses, leading to skewing toward an M1 or classically activated phenotype. Other activating cytokines include TNF-α, IL-1, IL-18, and GM-CSF, which provides a priming signal to augment AM differentiation and microbicidal activity.[96–98] Emerging evidence indicates that resident AMs display some degree of phenotypic plasticity, in that these cells can simultaneously display features of M1 and M2 (or alternative) activation during the evolution of inflammatory responses.[99]

Both oxidative and nonoxidative processes are used to kill ingested microbes. Alveolar macrophages display considerably less potent antimicrobial activity compared with blood monocytes and recruited exudate macrophages. Loss of granular peroxidase and a more modest respiratory burst account for reduced microbicidal activity. Resident AMs contain very little myeloperoxidase (MPO), and as a consequence the MPO-H_2O_2-halide system is less robust in resident AMs than in recruited macrophages. Microbes are also killed by macrophage-dependent nonoxidative mechanisms, including proteases, lysozyme, nitric oxide products, defensins, and cathelicidins. Late-phase killing of certain internalized bacteria, including *S. pneumoniae* and *H. influenzae*, ultimately requires induction of apoptosis in infected AMs.[100]

For effective killing of intracellular pathogens such as *M. tuberculosis* and certain fungi, resident AMs require cytokine signals elaborated by antigen-specific T cells during the adaptive immune response. Resident AMs can also develop long-term modifications of their immune phenotype after recovery from a prior infection, rending the host resistant to subsequent challenge by related or heterologous microbes, a form of trained immunity leading to "memory" AMs.[101,102] For example, recovery from *S. pneumoniae* results in enhanced long-term regional innate immunity to other pneumococcal serotypes, which is associated with augmented resident AM MHC class II expression, metabolic activity, and inflammatory cytokine production.[101] Conversely, prior exposure to viruses such as influenza can induce prolonged AM dysfunction, including impaired TLR signaling and reduced cell-surface C-type lectin and scavenger receptor expression.[103,104]

Innate Lymphoid Cells

A population of resident lymphoid cells, referred to as innate lymphoid cells (ILCs), are present in the respiratory tract.[41,42,105,106] These cells produce large amounts of cytokines early in response to microbial invasion and can be activated directly by microbial signals

Figure 120-3 Initiation and regulation of innate antimicrobial responses in the lower respiratory tract. PAMPs stimulate resident AMs to produce inflammatory cytokines and eicosanoids, including TNF-α, IL-1β, chemokines, and leukotriene B4, leading to the recruitment and activation of PMNs and exudate macrophages. Proximal cytokines induce gene expression and production of chemokines and growth factors by alveolar epithelial cells and other lung parenchymal cells. Microbes stimulate DCs and/or resident AMs to produce activating cytokines including TNF-α, IL-12, IL-23, IL-15, IL-18, and type I IFNs, leading to elaboration of IFN-γ, IL-17, and IL-22 by ILCs. Macrophage-derived signals can stimulate cytokine production from resident or recruited DCs. ILC can also be directly activated by PAMPs or DAMPs. Immunoregulatory molecules are released by AMs, ILCs, AECs, and myeloid-derived suppressor cells (MDSCs) to finely tune the magnitude of the innate response.

or host-derived cytokines without classic antigen presentation. Innate lymphoid cells, including NK, NKT, γδ T cells, and type 1, 2, and 3 innate lymphoid cells, drive protective local innate and adaptive immune responses in the lung (Figs. 120-3 and 120-4).

NK cells are present in large quantities within the lung, making up approximately 10% of the entire lymphocyte population. NK cells are also rapidly recruited to the lung in response to infection, where they are activated by cytokines, such as IL-12, IL-15, IL-18, TNF-α, and type 1 interferons produced by lung macrophages, DCs, and AECs.[107–109] Upon activation, NK cells produce robust quantities of TNF-α, IL-17, and IFN-γ, which are required for optimal cellular recruitment and pulmonary macrophage microbicidal activity during bacterial, mycobacterial, and fungal infection.[110] NK cells also mediate protective immunity during influenza infection via perforin-mediated lysis of virally infected cells and stimulate antimicrobial peptide release and epithelial regeneration via the elaboration of IL-22.[111] Overzealous innate responses by NK cells can sometimes be detrimental to the host, as is the case in respiratory syncytial virus (RSV) or influenza pneumonia.[108,112,113] The elaboration of IL-10 by NKs can paradoxically impair immunity against virulent bacterial pathogens such as *S. pneumoniae*.[114] Genetic deficiencies in NK cell function are associated with recurrent viral and bacterial infections, including those involving the respiratory tract.

Figure 120-4 Adaptive immune responses in the lungs develop in the draining lymph nodes and mucosa-associated lymphoid tissues, such as the bronchial-associated lymphoid tissue (BALT), both of which are organized into unique inductive and effector sites. DCs, macrophages, and B cells are the major APCs in the lungs. Monocytes contribute to the pool of newly recruited DCs through transendothelial migration in which peripheral blood monocytes differentiate into tissue DCs after crossing the vascular endothelium. Antigens in the airways and lung parenchyma are rapidly taken up and processed for antigen presentation by APCs on MHC class II to CD4+ T helper lymphocytes, which results in T cell proliferation. ILCs produce large amounts of cytokines early in a response that drive the polarization of Th1, Th2, Tfh, Th17, and Treg responses. By producing a distinct set of cytokines, each CD4$^+$ Th-cell subset helps shape the adaptive immune response, such as macrophage activation. With the "help" of Tfh cells, activated B cells in germinal centers undergo isotype switching and differentiation into plasma cells that secrete large amounts of antigen-specific effector antibodies.

NKT cells are a subset of unconventional αβ-T lymphocytes that recognize glycolipid rather than protein antigens that are presented by CD1d, a nonpolymorphic MHC class I–like antigen.[42,115,116] CD1d-restricted NKT cells can be activated directly by bacterial (*Streptococcus* spp.) or viral (IAV) glycolipids resulting in expression of TNF-α, chemokines, IFN-γ, and IL-17 required for microbial clearance.[117,118] In the lung parenchyma, NKT17 cells predominate. NKT cells can also be activated by host-derived cytokines, including IL-12, IL-18, IL-23, and type 1 interferons. Similar to NK cells, NKT cells can directly kill bacterial or virally infected cells in a perforin- and granzyme-B–dependent fashion. NKT cells have been shown to play a pivotal role in mucosal responses to viral (IAV, RSV), bacterial (*P. aeruginosa*, *Chlamydia* spp., *S. pneumoniae*), and fungal (*C. neoformans*, *A. fumigatus*) infection.[118,119] Importantly, different subsets of NKT cells can either augment or suppress the development of innate and acquired immunity, suggesting an important regulatory role of these cells during lung infection.

Mucosal-associated invariant T (MAIT) cells are a subset of predominantly CD8+ T cells that the recognize small molecules derived from the riboflavin metabolic pathway of bacteria, mycobacteria, and fungi and presented by the nonpolymorphic MHC class I molecule MR1.[42] MAIT cells are abundant in lung tissue, and these cells are major producers of type 1 and especially IL-17-related cytokines. Similar to NKT, MAIT cells can efficiently kill pathogen-infected cells. While the biologic role of these cells in human disease has not been well characterized, MAIT cells have been implicated in respiratory infections due to bacteria (*S. pneumoniae*), mycobacteria, and viruses (IAV).[120–122]

Gamma-delta T cells are a unique innate T-cell subset that are small in number (approximately 1%–2% of the total lung lymphocyte population) and localized to mucosal and epithelial surfaces. However, during respiratory infection the numbers of γδ T cells in the lung increase considerably (>30-fold), a process that is due primarily to local expansion rather than recruitment.[123,124] Upon activation by bacteria (*S. pneumoniae*, *K. pneumoniae*) and viruses, γδ T cells function as a rich and early cellular source of TNF-α, chemokines, IFN-γ, IL-17, and IL-22. The population of γδ T cells is rather heterogeneous, with specific subsets functioning to control the magnitude of DC and macrophage recruitment and activation during the resolution phase of pulmonary inflammation.[125] This nuanced response by γδ T cells is necessary to maintaining the immune and structural integrity of the lung during infection.

A subgroup of tissue-resident innate lymphoid cells (ILCs) has been more recently described that require the common γ chain of the IL-2 receptor and transcriptional repressor inhibitor of DNA binding 2 (Id2) for their development.[41] These lymphocytes lack the recombination-activating gene (RAG) and can be directly activated by cytokines released in the microenvironment during infection. There are three groups of ILC based on their predominant cytokine secretion profiles: group 1 ILCs produce the type 1 cytokine IFN-γ; group 2 ILCs produce type 2 cytokines such as IL-5 and IL-13; and group 3 ILCs produce IL-17 and IL-22. However, ILCs display considerable phenotypic plasticity, in that signals present in the lung microenvironment can skew the cytokine profile of ILC from one type to another. For example, during certain lung infections, resident or recruited ILC2s can convert to ILC1s by the myeloid-derived cytokines IL-12 and IL-18. ILC1s produce large amounts of IFN-γ and are thought to contribute to host defense against viral and bacterial pathogens.[126] ILC2s are activated by IL-25, IL-33, and thymic stromal lymphopoietin (TSLP) and participate in immunity against parasites. In addition, these cells secrete amphiregulin, a molecule that may contribute to respiratory epithelial repair during viral infection.[127] The prodigious production of IL-17 and IL-22 by ILC3s facilitates pathogen clearance and cytoprotection in lung infections due to bacteria such as *S. pneumoniae* and *K. pneumonia* and fungi (*C. albicans*).[128,129]

Alveolar Epithelial Cells

The alveolar–capillary membrane is a dynamic assembly of nontraditional innate immune cells that generate cytokines and chemokines required to recruit and activate specific inflammatory cells during microbial insults. In particular, alveolar epithelial cells (AECs) are key participants in the innate mucosal response to microbial challenge.[15,130] These cells express an array of both extracellular and intracellular signaling PRRs, including TLRs, NLRs, C-type lectins, and RIG-I. These PRRs trigger the release of a variety of inflammatory cytokines (IL-1, IL-6, IL-36 α/γ, type I and III interferons, GM-CSF) and chemokines (CXCL1, CXCL2, CXCL5, CXCL8, CCL2, CCL20) that regulate the engagement and activation of resident and recruited phagocytic cells.[11,38,96,97,130–132] AECs also highly express RAGE, which serves as a signaling receptor for the DAMPs HMGB1 and S100 proteins.[133] Like airway epithelial cells, AECs secrete molecules that directly mediate antimicrobial killing, include large antimicrobial proteins (lysozyme, lactoferrin, calgranulins A and B, SLPI) and small antimicrobial peptides (β-defensins, cathelicidins).[12,21] Type II AECs produce surfactant protein (SP)-A and SP-D, members of the collectin family of lectins. SP-A contains a carbohydrate recognition domain that binds to exposed carbohydrate residues on the surface of microbes, serving as an opsonin to promote internalization of diverse pathogens (Gram-positive and -negative bacteria, fungi, and viruses) by AMs and type II AECs.[93] SP-A also stimulates secretion of GM-CSF, promotes directed migration of AMs, and regulates macrophage oxidant production.[93,134] SP-D mediates agglutination of bacteria, fungi, and influenza virus, facilitating uptake by PMNs and other phagocytic cells.[135]

To maintain immune homeostasis, AECs function to tonically suppress potentially damaging inflammatory responses in the airspace. Immune suppression occurs through multiple mechanisms. Cell-surface CD200 expression by AECs functions to directly inhibit AM activation.[136] Trans-acting soluble factors secreted by AEC also exert suppressive effects on cells within the alveolus in a paracrine fashion. Inhibitory and cytoprotective molecules include cytokines such as IL-33, TGF-β, leukemia inhibitory factor, prostaglandins, lipoxins, resolvins, and surfactant proteins.[13,88,137,138]

AMPLIFICATION AND REGULATION OF THE INFLAMMATORY RESPONSE TO MICROBIAL INVASION

A dual phagocytic system involving resident and recruited macrophages and recruited PMN is required for the clearance of bacteria from the lower respiratory tract (Fig. 120-3). Neutrophils ingest microbes by phagocytosis.[139] Effective killing requires products of granule constituents and molecular oxygen. Hydrogen peroxide and reactive oxygen intermediates are involved in neutrophil-mediated killing. The MPO-H_2O_2-halide system is a crucial participant in oxygen-dependent killing by neutrophils. Granule components also are crucial in PMN-mediated microbial killing. Microbicidal molecules found in azurophil granules include lactoferrin, lysozyme, cathepsin G, elastase, and cationic proteins such as α-defensins and cathelicidins. Neutrophil extracellular traps (NETs) are complex structures composed of nuclear chromatin, histones, and a variety of granular antimicrobial proteins.[140,141] NETs are released from azurophilic granules during infectious challenge and are capable of physically ensnaring bacteria. These structures facilitate the interactions between bacteria and antimicrobial effectors, ultimately leading to enhanced bacterial killing.[142] NETosis (this regulated form of neutrophil cell death) is stimulated by both microbial components and endogenous molecules, including the antimicrobial peptide LL37, the DAMP HMGB1, and reactive oxygen species.[24] While NETosis in general enhances the containment and killing of pathogens, uncontrolled NET formation can mediate collateral damage to lung structures, as has been observed in severe H1N1 and SARS-CoV-2 pulmonary infection leading to ARDS.[143] Moreover, certain extracellular bacterial pathogens such as *S. aureus* and *S. pneumoniae* can subvert the microbicidal effects of NETs by inhibiting NET formation and elaboration of pathogen-derived protease that degrade NETs.[144]

Recruitment of PMNs from the blood into the alveolus is initiated by upregulation of selectins and β-integrins on the surface of leukocytes and endothelium, concurrent with the establishment of chemotactic gradients within the lung interstitium and alveolar space.[87] Chemotactic gradients are established in part by matrilysin-mediated shedding of syndecan–chemokine complexes into the alveolar space.[145] Early recruitment of PMNs to the lung (<4 h) is directed by cytokines, chemokines, and leukotrienes secreted by resident AMs, whereas sustained neutrophil influx (24 h) appears to be driven by chemokines produced by lung structural cells, including AECs.[146] CXC chemokines that mediate PMN influx during lung infection include CXCL1, CXCL2, and CXCL5 in the rodent and CXCL8 in humans.[87,146,147]

Recruited or exudate macrophages represent an essential arm of the innate response in bacterial and fungal infection of the respiratory tract. The recruitment of these cells to the lung requires specific chemokines and chemokine receptors. In particular, CCL2 and its receptor CCR2 mediate the influx of exudate macrophages in bacterial pneumonia.[148] CCL2 also serves as an autocrine inducer of cytokine (G-CSF) and CXC chemokine (CXCL1, CXCL2) production from AMs, further amplifying the neutrophilic response during pneumonia.[149] CCL3 participates in both exudate macrophage and PMN recruitment during bacterial infection.[150] Recruited macrophages represent a heterogenous group of inflammatory cells, with a distinct pool of exudate macrophages displaying a highly activated phenotype, function as antigen-presenting cells, and produce robust amounts of inflammatory cytokines. In addition to direct antimicrobial properties, these inflammatory macrophages network with resident lung cells, including ILCs and AECs via elaboration of proximal cytokines such as TNF-α.[129] Exudate macrophages can also network with recruited PMNs to optimize type 1 cytokine responses in bacterial pneumonia.[151] A separate pool of recruited macrophages exhibit enrichment of genes involved in protein processing and proteolytic activity and are believed to function in a reparative role during resolution of inflammation.[99]

Sentinel DC and macrophages produce IL-12, IL-15, IL-18, IL-23, and type 1 interferons within minutes to hours after exposure to LPS and other microbial products. IL-12, IL-15, and IL-18 induce the release of IFN-γ from ILCs early in the innate response and antigen-specific T cells later in the adaptive response. IL-23 triggers rapid (hours) production of IL-17 and IL-22 from tissue-resident γ/δ, NKT, MAIT, and ILC3.[41,42,152] IL-17 promotes production of IL-1, IL-6, TNF-α, CXC chemokines, IL-22, and antimicrobial peptides from ILCs, AMs, and cellular constituents of the alveolar–capillary membrane.[152,153] IL-1 family members, including IL-1 and IL-36α/β, also serve as relevant proximal signals leading to DC activation and induction of cytokines and chemokines from myeloid and structural cells of the lung.[154]

Robust innate responses are required for effective control of pathogens at mucosal sites of invasion. However, these responses need to be tempered to allow for protection and restoration of lung architecture. Deleterious innate immune activation within the lung is characteristic of infections due to certain viruses (H1N1, avian influenza, SARS-CoV-2) and bacteria (cytotoxic strains of *P. aeruginosa*).[155] The cytokine storm that occurs in response to viral infections such as SARS-CoV-2 may be mediated, in part, by inhibition of autophagic responses in immune cells, leading to inflammasome activation and release of inflammatory cytokines.[156] Specific cells and soluble factors present within the lung microenvironment contribute to the fine-tuning of innate responses. For instance, surfactant proteins A and D and soluble forms of PRRs can antagonize binding of DAMPs and PAMPs to toll like receptors or C-type lectin receptors, hence reducing inflammatory mediator release.[157–159] Inhibitors of downstream TLR signaling, such as IRAK-M, suppress deleterious inflammation in influenza infection.[160] Anti-inflammatory molecules, including IL-10 and IL-1 receptor antagonist, produced by NKT, $\gamma\delta$ T cells, exudate macrophages, and myeloid-derived suppressor cells, contribute to the resolution of inflammation.[161,162] Finally, the update of apoptotic neutrophils and other cells by lung macrophages signals an anti-inflammatory program that facilitates tissue repair.[163]

LUNG ADAPTIVE IMMUNE RESPONSES

Adaptive immune responses consist of two major effector systems, antibody- and cell-mediated immunity, which are generated by antigen specific B and T lymphocytes, respectively. B and T lymphocytes rearrange their immunoglobulin and T-cell receptor (TcR) genes to generate upward of 10^{11} and 10^{14} different clones of B and T lymphocytes that each express a distinct antigen receptor. The antigen receptors on B lymphocytes recognize native antigens including carbohydrates, proteins, and simple chemical groups, while the antigen receptors on T lymphocytes recognize only peptides derived from protein antigens bound to cell-surface proteins from the major histocompatibility complex (MHC) on antigen-presenting cells (APCs). Antigen-specific immune responses require at least 7 to 10 days for their development; this time is required for the proliferation and differentiation of antigen-specific T and B lymphocytes. During the development of specific immune responses, pathogens may continue to grow in the host or be held in check by innate and inflammatory mechanisms.

Adaptive immune responses in the lungs develop in the draining lymph nodes and mucosa-associated lymphoid tissues, both of which are organized into unique inductive and effector sites. Inductive sites include specialized lymphoid follicles underlying the epithelium, such as nasopharynx-associated lymphoid tissue (NALT) and bronchial-associated lymphoid tissue (BALT) in the upper and lower airway, respectively, and Peyer's patches and isolated lymph follicles in the gut, and downstream lymph nodes, including cervical and mediastinal lymph nodes (LN) draining the respiratory mucosa and mesenteric LN draining the intestinal mucosa.[164,165] Clones of lymphocytes are triggered by APCs to proliferate and differentiate into effector cells. Antigen-specific lymphocytes remain expanded after elimination of an infection (memory lymphocytes). Memory lymphocytes provide a much more rapid response to a second exposure to antigen.

Antigen Presentation and Antigen-Presenting Cells

Antigen-presenting cells (APCs) and innate lymphoid cells (ILCs) provide an essential link between innate and adaptive immunity (Fig. 120-4).[166–174] Antigens in the airways and lung parenchyma are rapidly taken up and processed for antigen presentation by one of two pathways.[175] The endocytic pathways process protein antigens obtained from the extracellular space in phagolysosomes converting them to small polypeptides. The polypeptides are loaded onto MHC class II molecules to prime APCs for further presentation to MHC class II–restricted CD4+ T helper lymphocytes. The endogenous pathway processes peptides from the intracellular environment and loads them onto MHC class I molecules for presentation to MHC class I–restricted CD8+ T cells.

Dendritic cells, macrophages, and B cells are the major APCs in the body. Immature DCs have very active constitutive macropinocytosis, a nonspecific process through which the cell can internalize extracellular material, and this is believed to be a major mechanism of antigen acquisition by DCs.[176] As a result, DCs are very efficient APCs.[177] In contrast, B cells have little macropinocytic activity and rely almost exclusively on receptor-mediated endocytosis for antigen uptake. B cells with antigen-specific surface-bound immunoglobulin (B cell receptor, BCR) are 1000 times more efficient in processing and presenting antigens to T cells than B cells encoding BCRs for an irrelevant antigen.[178] B cells and macrophages also have cell-surface Fc receptors for IgG (FcγRs), as well as complement receptors, that are involved in both clathrin-dependent and -independent antigen internalization, processing, and presentation.[176] Macrophages, DCs, and B cells also express lectin receptors, such as the mannose receptor and DEC205, that bind carbohydrate residues on some microbes and target them for uptake either by clathrin-dependent endocytosis or by phagocytosis. For macrophages and some subsets of DCs, phagocytosis is an important mechanism of foreign antigen uptake. However, plasmacytoid DCs (pDCs) have severely compromised phagocytosis compared with conventional DCs (cDCs).[176] As noted above, phagocytosis can also be mediated by receptors such as C-type lectins, Fc receptors, complement receptors, scavenger receptor A, and CD36, which recognize ligands on pathogens and apoptotic cells. More recently, there has been interest in the role of macroautophagy in internal Ag acquisition by MHCII on APCs. Mutation of autophagy gene 5 (ATG5) in DCs render them unable to activate virus-specific CD4+ T cells, which suggests a role for macroautophagy in APC activity by DCs. Thus, DCs, macrophages, and B cells use various different cellular processes to capture and deliver diverse antigens as APCs.

Dendritic cells are the most potent APCs for T cells. DCs are bone marrow–derived cells that take up residence in peripheral tissues at epithelial borders throughout the mammalian host, where they become specialized for recognition of pathogens and microenvironmental tissue damage during antigen uptake and presentation. Following antigen uptake, they migrate to lymph nodes or mucosa-associated lymphoid tissue. Two broad subsets of DC have been identified:[166,179,180] conventional DC (cDCs) and plasmacytoid DC (pDCs). mDC express CD11c, CD11b, and varying levels of MHC class II and costimulatory molecules (CD40, CD80, and CD86). Human pDCs express blood DC antigen (BDCA)-2, whereas murine pDCs express CD11c, GR-1, and B220. cDCs contribute to a variety of T-cell responses or tolerance, and pDCs have been implicated in antiviral immunity and in murine models of asthma. The predominant DC subset involved in host defense against pathogens is the cDCs.

DCs exist in both immature and mature forms.[181] Immature DCs are concerned mainly with antigen capture. DCs are mobilized from bone marrow precursors to peripheral blood in response to pulmonary inflammation. Monocytes contribute to the pool of newly recruited DCs through transendothelial migration in which peripheral blood monocytes differentiate into tissue DCs after crossing the vascular endothelium. CCR2 is a critical receptor in the recruitment of DCs during inflammatory responses. CCR6 mediates recruitment of DCs specifically to the airways and alveolar space in response to CCL20 secreted by respiratory epithelial cells.[182] DC maturation is dependent on sensing of infection,[166,179,180] which may occur directly by detection of pathogen products using PRRs, activation by inflammatory signals such as TNF-α, or indirectly through exposure to DAMPs. Mature DCs upregulate MHC class II and costimulatory molecules allowing a phenotype focused on antigen presentation and the stimulation of naïve T cells.

DC maturation is accompanied by changes in the expression of chemokine receptors.[166,179,180] CCR1, CCR2, CCR5, and CCR6 are downregulated. CCR7 expression is enhanced, allowing DCs to respond to chemokine gradients of CCL21 and CCL19 emanating from local lymphatics and draining lymph nodes. Mature DCs leave the local inflammatory environment carrying their antigenic load to draining lymph nodes. DC–T-cell interactions within the draining lymph node are complex.[183] T-cell stimulation, proliferation, and activation result if antigen recognition occurs. Induction of Th1, Th2, Th17, Tfh, or T-regulatory responses may be the end result.[170,172,184]

The engagement of PRRs on DCs leads to increased expression of MHC-peptide complexes and costimulatory molecules as well as the production of immunomodulatory cytokines, all of which have a profound effect on T-cell priming and differentiation.[166,179,180] Triggering of the T-cell receptor (TCR) occurs following an interaction with an antigen/MHC complex and provides “signal one” to the T cell. T-cell maturation results in upregulation of important costimulatory molecules. Specifically, DCs increase the expression of B7.1 (CD80) and B7.2 (CD86), which bind CD28 on T cells providing “signal two” to activate antigen-specific T cells.

■ T Cells and Adaptive Responses

For decades, CD4 Th cells were believed to be the most significant sources of regulatory cytokines shaping the development of immune responses in the lung; however, ILCs produce large amounts of cytokines early in a response that drive the polarization of Th1, Th2, Tfh, Th17, and Treg responses.[185–187] These cells produce many of the same cytokines as CD4 Th cells, but they do not express a T cell receptor or cell surface markers associated with other lineages. Thus, they are not antigen-specific. Activation of ILCs is an important step in the development of adaptive immunity and polarization of T-cell responses.

$CD4^+$ T cells coordinate antigen-specific immune responses against inhaled antigens.[170–174,179] Separate, distinct subsets of $CD4^+$ T helper (Th) cells mediate a variety of distinct adaptive immune response “programs” (Fig. 120-4). Antigen exposure can initiate the afferent phase of the adaptive immune response that includes all subsequent events that lead to the formation of a poised antigen-specific response. The priming of $CD4^+$ Th cells from naïve precursor $CD4^+$ T cells is a critical component of the afferent phase. $CD4^+$ Th cells aid B cells in the production of antibodies that mediate components of the hypersensitivity reaction. Endowed with antigen-specific receptors, T cells and antibodies mediate the efferent phase of the adaptive immune response that encompasses all the immune activities directed at the antigen source. APCs acquire antigen at the site of introduction and migrate to draining lymph nodes and BALT to prime naïve $CD4^+$ T cells. Naïve $CD4^+$ T cells undergo multiple rounds of division and progress through multiple stages of differentiation along the pathway to becoming effector $CD4^+$ Th cells.[188–190]

$CD4^+$ Th cells differentiate into one of several distinct subsets that in turn mediate a distinct adaptive immune response “program.”[185–187] Each program has a genetic foundation in $CD4^+$ Th cells. Master regulation by a specific transcription factor promotes the acquisition of a particular Th phenotype at the expense of the other phenotypes. Tbet (Tbx21) promotes Th1 development, GATA3 promotes Th2 development, and RORγT promotes Th17 development. Likewise, $CD4^+$ T regulatory (Treg) cells that inhibit $CD4^+$ Th activity to limit harmful inflammation are specified by the transcription factor Foxp3. During $CD4^+$ Th cell activation, the cytokine milieu present (from DCs and ILCs early in the response and other inflammatory cells during chronic inflammation) guides cellular differentiation along one of the particular pathways. IL-12 along with IFN-γ promotes Th1 cell development, IL-4 promotes Th2 cell development, and the combination of TGF-β and IL-6 promotes Th17 development. IL-23 drives the expansion of the Th17 cell population. The presence of TGF-β alone supports the differentiation of Treg cells.

Cytokine production represents a key effector function by which $CD4^+$ Th cells coordinate adaptive immune responses.[185–187] By producing a distinct set of cytokines, each $CD4^+$ Th cell subset coordinates a distinctive adaptive immune response program that likely developed evolutionarily to counter a particular pathogenic threat. Th1 cells produce IFN-γ, along with IL-2 and TNF-α, and help protect against intracellular pathogens, but also mediate delayed-type hypersensitivity. Th2 cells produce IL-4, IL-5, and IL-13 and promote a response to parasite infection and responses where mucus shedding and expulsion are beneficial, as well as humoral immunity. Th17 cells produce IL-17 required for protection against several extracellular pathogens.

Th2 cells have long been regarded as the main providers of help for isotype switching, cellular proliferation, and antibody production by B cells.[185–187] However, it is now appreciated that Tfh cells are the primary “helper” cells for B cells in vivo. Tfh and Th2 cells share numerous features and signaling pathways and may develop from a common precursor, as exemplified by studies that demonstrated impaired development of both types of T cells in mice with targeted knockouts of the genes encoding MaF, ICOS, and IL-21R. However, Tfh cells can be clearly distinguished from Th2 cells by their increased expression of both CXCR5 and BCL-6 and by their reduced expression of BLIMP1 and CCR4; the latter is a Th2 cell–associated chemokine receptor. Similar to Th2 cells, Tfh cells can express IL-4.

■ B Cells and Adaptive Responses

The antigen specificity of an antibody molecule is generated by the rearrangement of heavy and light chain gene segments, which ultimately encode the amino-terminal domains of the heterodimeric antibody protein. Each B cell secretes a single type of antibody molecule as a result of these genetic rearrangements within that cell, which recognizes a single epitope on a microbial Ag. Antibodies are proteins that readily move from the circulation through tissues and into lymphatic drainage. It is not inaccurate to describe the lung tissue as being bathed in circulating antibodies. Antibody isotype and effector functions are determined by the carboxy-terminal domain of the protein, known as the Fc region. Each of the antibody isotypes (IgM, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, or IgE) binds to one or more receptors, via Fc region binding to an Fc receptor, expressed by an effector cell of innate immunity (such as AMs or recruited neutrophils). This has the effect of pointing the antigen-binding site away from the cell and "imparting" microbial Ag specificity to an effector cell. This makes it possible for different microbial antigens to activate different effector functions of innate immunity such as phagocytosis, degranulation, complement activation, or transcytosis across the epithelium. Antibodies are also critical for blocking binding of microbial toxins and viruses to cells in the vasculature, lungs, and other organs. Some antibody isotypes are more closely associated with allergic and antiparasitic responses (IgE), mucosal protection (IgA), anticapsular bacterial responses (IgM), and antibacterial and antiviral responses (IgG).

Antibodies can be either secreted or surface-bound, which is dependent on the differentiation state of the B cell. The surface-bound immunoglobulin molecule on a B cell and its intracellular signaling complex is often termed the B-cell receptor (BCR). B cells differentiate from hematopoietic stem cell precursors, initially becoming immature B cells (expressing IgM and IgD isotype antibodies on their surface) that emerge from the bone marrow and circulate through the peripheral blood, lymphoid organs, and tissues (such as the lungs). If B cells specifically bind to a microbial Ag via their BCR in the periphery, these B cells become activated and can proliferate to form discrete structures called germinal centers in secondary lymphoid tissues or BALT. Most Tfh cells and most IL-4 production is localized to germinal centers.[185,187,191,192] The processes of somatic hypermutation, class switch recombination, and affinity maturation of activated B cells all occur in germinal centers, as well as differentiation of memory B cells and plasma cells.

After interaction with Ag-primed DCs, Tfh cell precursors migrate to the T cell–B cell border in the white pulp of secondary lymphoid organs to form germinal centers to provide help for B cell maturation. Tfh cells home to B cell follicles owing to their expression of CXCR5, and CXCR5$^+$ Tfh cells isolated from secondary lymphoid tissue can produce cytokines that support B cell differentiation. In the absence of T cell help during B cell priming, B cells will undergo apoptosis, rather than differentiation into germinal center B cells or plasma cells. Tfh cells also express high levels of inducible T cell costimulator (ICOS), programmed cell death 1 (PD1), the transcriptional repressor B cell lymphoma 6 (BCL-6), and cytokines that influence B-cell differentiation and antibody production such as IL-21 and IL-4. Human Tfh cells have also been reported to express IL-10, which also plays a role in the differentiation of human B cells, and high levels of the chemokine CXCL13.

With the "help" of Tfh, activated B cells in germinal centers undergo isotype switching, which enables them to utilize a different immunoglobulin constant region for the same antigen-binding specificity, resulting in production of a different antibody isotype (e.g., IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, IgE). Long-lived B cells are a critical arm of durable immunity to respiratory pathogens.

As mentioned previously, B cells can act as APCs. B cells endocytose whole antigen (via their BCR) and then present degraded peptide fragments to antigen-specific T cells in association with MHCII. B cells are less efficient APCs than DCs and other myeloid cells;[193] however, B cells are highly selective APCs because the endocytosed Ag must be bound by the Ag-specific BCR to initiate the process. Thus, in Tfh–B and Th2–B interactions, the T cells recognize the same antigen as the B cell, which can significantly amplify an antigen-specific response.[194]

Efferent Immune Responses and Regulatory T Cells

Antigen-specific T cells must migrate via the bloodstream to peripheral sites of ongoing infection.[174,195] Chemokine–chemokine receptor and adhesion molecule–ligand interactions are involved. While DCs often migrate to local lymphoid tissue after activation, a subset of recruited DCs remains in the lung rather than migrating to draining lymph nodes.[171,179,196] These recruited nonmigratory pulmonary DCs present antigen to newly recruited T cells to drive T-cell polarization and stimulate cytokine release. Cytokines produced by specific CD4 and CD8 lymphocytes play a central role in the ongoing recruitment of inflammatory mononuclear phagocytes and other effector lymphocytes.

Viruses including influenza, parainfluenza, RSV, Hantavirus, coronavirus, herpesvirus, and CMV cause significant pulmonary disease. Viruses are intracellular pathogens; the killing of virally infected cells by MHC class I–restricted cytotoxic CD8 T lymphocytes (CTLs) is required. CTLs kill target cells by two mechanisms (Fig. 120-5). Cytolytic mediators, including perforins and granzymes, are released from cytoplasmic granules. Perforins induce pore formation and osmotic cell lysis, and granzymes are proteases that activate cell caspases, resulting in apoptosis. Killing of virally infected cells can also result from the direct induction of apoptosis by Fas–Fas Ligand binding, which is upregulated and present on CTL.

The development of cell-mediated immunity to viral infections precedes by mechanisms presented earlier but may also precede locally within the lung. Priming can occur in bronchus-associated lymphoid tissue (BALT), a submucosal lymphoid tissue found in the major bronchi.[164,165] Localized priming of the cell-mediated immune response may play a crucial role in viral host defense.

Memory T-cell responses are important in certain viral illnesses and following administration of antiviral vaccines.[173,174,190] Subsets of memory T cells have been defined.[197] Effector memory T cells are found within the lung, are short lived, retain markers of activation, and have effector functions; these cells lack expression of lymphoid trafficking molecules CCR7 or CD62L. Central memory T cells reside predominantly within lymphoid organs, persist for long periods of time, and express CCR7 and CD62L.

The immune system possesses various mechanisms to control and regulate inflammation and adaptive responses to prevent and minimize reactivity to self-antigens or an overexuberant response to a pathogen. One of these mechanisms is through the generation of Treg cells.[198,199] CD4+CD25+ T reg cells are the best-characterized subset. These cells represent 5% to 10% of the CD4+ T lymphocytes in healthy adult mice and humans. CD4$^+$ Treg cells are recognized for the production of cytokines with anti-inflammatory activity, including IL-10 and TGFβ, and are able to limit CD4$^+$ Th responses.

There are a number of subsets of Treg cells, with the major distinction being (1) Tregs that are induced in the periphery following antigen encounter (inducible Tregs, iTreg) and (2) Tregs that arise from normal T-cell thymic development (naturally occurring Tregs, nTreg).[200–202] Both types of regulatory T cells have been shown to play a role in mucosal inflammation and infection. Activated Treg cells can suppress not only antigen-specific responses but also unrelated immune responses in a non-antigen-specific manner either through cell contact or through the regulatory cytokines they produce—a mechanism known as bystander suppression.

nTreg cells can prevent immunopathology in a variety of infections, and the mechanisms by which nTreg cells regulate inflammation appear to vary between stimuli and include cell contact and soluble mediators.[200–202] Activated nTreg cells efficiently control self-reactive T cells and innate responses (thereby limiting tissue damage)

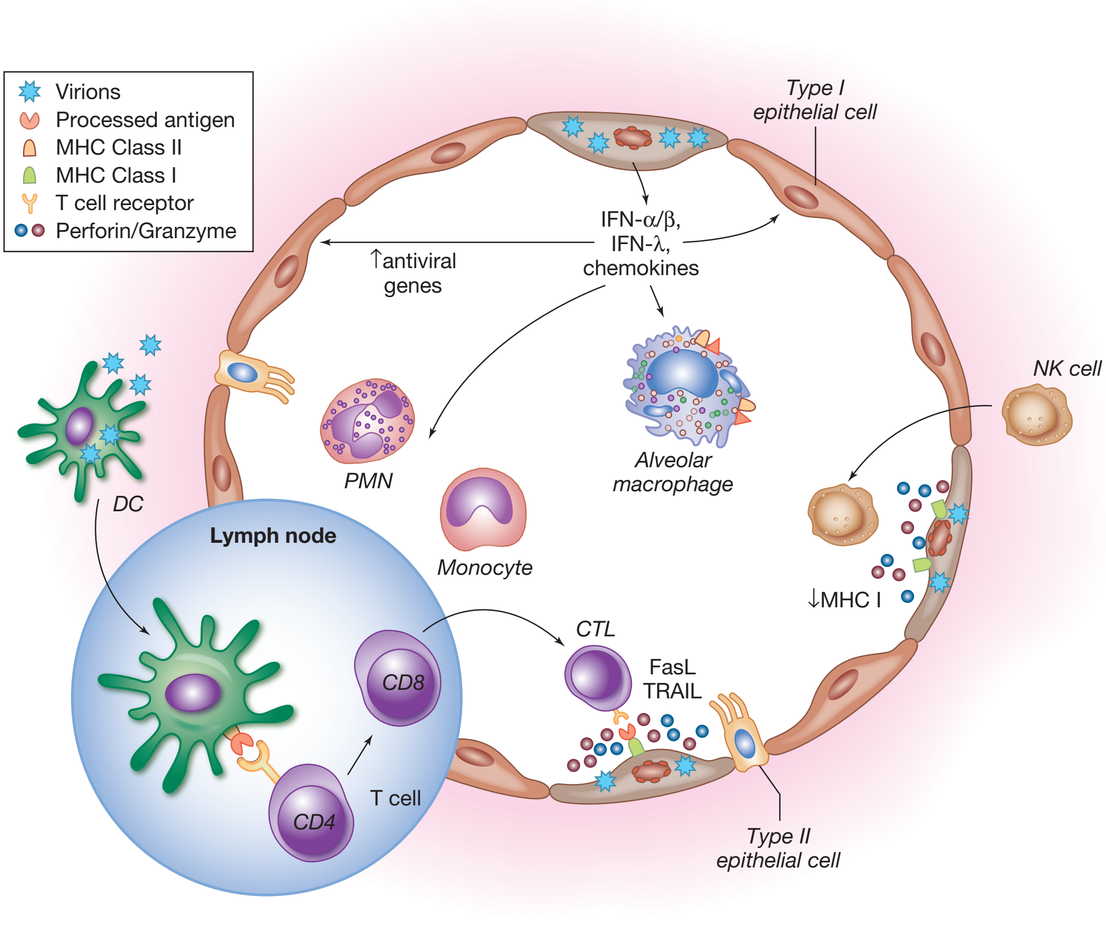

Figure 120-5 Viral infection of the lower airways initiates a cascade of events leading to antiviral immunity. One of the earliest steps is the production of type I interferons (IFN-α/β) by infected epithelial cells, as well as other cytokines, that can activate alveolar macrophages, uninfected epithelial cells, recruited inflammatory cells, and DCs. Virus antigen uptake by DCs in the lungs, along with inflammatory signals, results in migration of DCs to the draining lymph nodes or BALT where viral Ag is processed and presented to Ag-specific CD4 Th1 cells that become activated and clonally expand. These Th1 cells provide additional signals for the proliferation and activation of virus-specific CD8 cytolytic T cells (CTLs). These CTLs can lyse cells in the lungs that are virally infected by targeting MHCI molecules that have bound processed viral Ag (viral peptides). If a CTL is activated, it can lyse a virally infected cell using perforin- and granzyme-mediated mechanisms or by inducing apoptosis. To evade detection, some viruses cause a downregulation of MHCI expression on cells. However, NK cells specifically target cells that have lost MHCI expression and lyse them through similar mechanisms as CTLs.

in mouse models of chronic infection and inflammation. nTreg cells, however, can also inhibit allergen-induced airway hyperreactivity through IL-10–dependent mechanisms or by inhibiting antigen presentation by DCs. The antigen specificity of iTreg cells is largely microbial or environmental antigens, whereas the nature of the antigens recognized by nTreg cells is not clear. nTreg cells are believed to recognize a wide array of self-antigens as a consequence of their development and selection in the thymus. During the onset of acute disease, nTreg cells have the potential to recognize self-antigens that are released by tissue damage; however, evidence from chronic infection suggests that nTreg cells can also recognize microbial antigens.

iTreg cells are generated in the periphery during an immune response and act in an antigen-specific manner.[200–202] Several subsets of iTreg cells have been defined, and iTreg cells do not constitutively express Foxp3 or CD25 but can express high levels upon activation. Foxp3 appears to act as a cell lineage differentiation factor because it correlates closely with suppressor activity, irrespective of CD25 expression. iTreg cells are often the most potent source of IL-10 in downregulating inflammatory responses to infections or allergens.

Depending on their stage of differentiation, B cells can be activated to perform an array of cellular functions, in addition to antibody production and antigen presentation. B cells can be induced to express costimulatory molecules, such as CD80, CD86 and CD40, which promote the interaction with T helper cells, including activation of proinflammatory cytokine secretion. Subsets of B cells also produce a number of cytokines, including lymphotoxin-α, IL-6, and TNF-α, which can help create the inflammatory milieu in the lungs and GCs that promotes local polarization of Th1 and Th17 cells.[203] Other subsets of B cells (regulatory B cells) produce anti-inflammatory cytokines, such as IL-10 and IL-35.[204] Ultimately, B cells that develop during infection in the lungs and draining lymph nodes can play a role in promoting or damping inflammation in the lungs.

Long-term B cell immunity to respiratory infection involves both plasma cells (typically found in the bone marrow) and memory B cells in the lungs and other peripheral sites, both of which require T-cell help in germinal centers for their development.[192,205] B cells can stop proliferating in a germinal center, differentiate into memory cells, and migrate to mucosal surfaces in preparation for subsequent encounter with their microbial antigen.[206] There is tissue-specific selectivity for memory B cell homing, and lung-resident B cells have hallmarks of resident memory cells, such as the expression of CD69, and respond more quickly to reinfection than those from lymphoid organs.[206] It has recently been demonstrated in a murine influenza infection model that influenza-specific resident memory B cells develop early after infection and are phenotypically distinct from memory B cells in secondary lymphoid tissue.[207] The development of these lung-resident memory B cells is dependent on the presence of Ag and CD40 signaling, and these cells appear to develop in the germinal centers of the BALT of influenza-infected mice. In terms of timing of the response, germinal centers develop in the draining lymph nodes very rapidly after infection, whereas germinal centers develop more slowly in lung tissue because it takes time to form inducible BALT.[208] Ultimately, the presence of resident memory B cells in the lung allows for a rapid secondary response (antibody secretion) in the lung following subsequent infection.

Lung-resident memory T cells are also a critical element of long-term pulmonary immunity, and these T cells must physically interact with MHC-expressing cells (either as target cells or APCs) in a secondary response in order to exert their effector functions.[209] Thus, both resident memory T cells and resident memory B cells in the lung contribute to protection against secondary pulmonary infections. Immunoglobulins are clearly present in the epithelial lining fluid of the lower respiratory tract. Serum IgG can clearly gain access to the alveolar space in normal subjects and during inflammation when large changes in alveolar permeability occur. Systemic immunization enhances pulmonary clearance of many bacteria in animal models, and enhanced clearance correlates with the appearance of antibodies in serum and bronchoalveolar lavage fluid that are directed against the organisms. Thus, it seems likely that alveolar antibodies can be derived from the serum. However, there is one intriguing hypothesis about optimal antibody production from the previously discussed research,[207] which is that for respiratory infections by influenza, SARS-CoV-1, SARS-CoV-2, and others, optimized vaccines designed to elicit highly effective, long-lived protection against respiratory viral infections may need to have some level of antigen sequestration in the respiratory tract, as would be seen in recovery from a live infection.

Circulating antibody (immunoglobulin) is the most widely recognized effector molecule produced by B cells. Immunoglobulins are a major protein constituent of the fluid that lines the luminal surface of conducting airways and alveolar lining fluid. Effector functions for antibodies include opsonization, complement fixation, antibody-dependent cellular cytotoxicity (ADCC), agglutination, and neutralization. Approximately 20% of the total protein present in bronchoalveolar lavage fluid consists of IgG, IgM, and IgA. IgA is the predominant immunoglobulin in secretions of the trachea and major bronchi, while both IgG and IgE are present as well. IgG is the predominant immunoglobulin in alveolar lining fluid. Antibodies function as (1) opsonins that allow phagocytes to recognize and ingest microbes via the involvement of Fc receptors; (2) activators of complement, which enhances opsonization and leads to direct lysis of some bacteria; and (3) neutralizing antibodies that neutralize pathogens or their toxins by binding to microbes or their products, thereby preventing injury to cells. Specific antibody is an important component in lower respiratory tract defenses against extracellular microbes. Many extracellular bacteria possess polysaccharide capsules that allow them to evade phagocytic cells.

Numerous species and strains of bacteria and fungi have evolved the capacity to invade and survive within host leukocytes, primarily macrophages, to evade recognition and elimination by innate immune responses. Cell-mediated immunity is required to successfully eradicate these microbes. Cytokines produced by CD4 and CD8 T lymphocytes play a central role in the activation of microbicidal function in phagocytic cells (Fig. 120-4). IFN-γ produced by both CD4 and CD8 T lymphocytes is the most important macrophage-activating factor. Macrophage activation is further enhanced by TLR stimulation and by inflammatory cytokines such as TNF-α and GM-CSF. Activated macrophages kill intracellular microbes by exposure to toxic acid hydrolysis and cationic peptides in phagolysosomes, enhanced nitric oxide and reactive nitrogen intermediate production, and induction of the respiratory burst. Macrophage apoptosis in response to intracellular infection has been shown to be of importance in blocking cell-to-cell spread of certain intracellular infections.

Granuloma formation is an important mechanism of host defense to intracellular microbes.[210,211] The recruitment of monocytes and lymphocyte populations to the site of infection is required for granuloma formation. Macrophages coalesce into large, epithelioid, and multinucleated giant cells. DCs, CD4+ T lymphocytes, and CD8+ lymphocytes form a loose meshwork that serves to contain microorganisms. Granulomas are sites of ongoing production of inflammatory cytokines, including TNF-α, IFN-γ, and chemokines capable of recruiting additional effector cells.

CONCLUSION

Infections are the evolutionary force for the development of a complex system of pulmonary host defenses. A coordinated response of many different cells is required for the lung to clear pulmonary pathogens. An increasingly complex and potentially injurious cascade of host responses is mobilized following pulmonary microbial challenges. Although the interactions of microbes in the host are invariably complex, models of pulmonary infection have provided crucial information regarding the regulation of inflammatory and immune responses. These insights should eventually allow the development of rational strategies regarding vaccination and immunotherapy. The use of animal models offers the possibility of understanding the mechanisms that regulate immune responses sufficiently well so that the response to a specific antigen could be controlled. A more complete understanding of host defense will allow the stimulation of deficient responses and the suppression of harmful responses to microbial pathogens and other antigens that enter the lung.

CHAPTER 121

The Lung Microbiome

John E. McGinniss
Joshua M. Diamond

INTRODUCTION

The use of novel methods to study the microbiome has revolutionized our understanding of the microbial communities that reside on mucosal surfaces. While culture-based methods and Koch's postulates produced advances in medicine that moved the field into the modern era through development of antimicrobials and an understanding of microbial pathogenesis, these methods are inherently biased and reductive in scope.

This chapter constitutes an introduction to the methods used in microbiome research. Highlighted are specific considerations for lung research, as well as what is known about the lung microbiome in health and selective disease states. Table 121-1 outlines terms used in this chapter and commonly employed in the microbiome literature. Since this is a rapidly evolving field, inevitably, we will witness advances in a variety of areas. Understanding microbiome composition in disease states, identifying predictive microbiome features, and establishing prognostic biomarkers, host–microbiome interactions, and, potentially, therapeutics that affect the microbiome or that are microbially derived, are reasonable goals. Given the dynamic nature of the field, our objective is to provide an overview of foundational principles, to highlight considerations for understanding the microbiome in the lung, and to suggest future directions in lung microbiome research.

METHODS OF STUDYING THE LUNG MICROBIOME

Advances in sequencing technology ("next-generation" or "deep sequencing") and computational methods have enabled wide application of comprehensive, unbiased, culture-independent approaches to the study of the lung microbiome.[1] The earliest and most widely used approach amplifies the bacterial 16S rRNA gene.[2–5] PCR amplification uses primers targeting conserved sequences; within the 16S rRNA gene are hypervariable regions whose sequences vary between bacteria. Therefore, sequencing data allows identification of the various bacterial members of the community.[1,5] Sequence-based approaches are quantitative and capture both recognized pathogens and commensals. Targeted 16S rRNA gene analysis also captures archaea, which are scant in the lung and generally understudied. Fungi (the "mycobiome") are studied using analogous targeting of regions shared by all fungi, such as the 18S rRNA gene or internal transcribed spacer (ITS) sequence in the ribosomal gene locus. In contrast, viruses have no such universally shared sequences. Figure 121-1 outlines the main steps in conducting a microbiome study.

A complementary approach is *shotgun metagenomic sequencing*, which sequences all the DNA (or RNA, depending on sample preparation) in a specimen. Thus, shotgun sequencing can be used to profile viruses (the "virome"), as well as fungi and bacteria. Another benefit of shotgun sequencing is that it captures microbial gene content that enumerates the genetic potential for microbial functions (e.g., metabolic activity, virulence factors, antimicrobial resistance). Large amounts of host DNA relative to microbial DNA in many lung samples often results in increased cost of data acquisition and complexity of analysis,[6] although with recent advances, shotgun metagenomics enjoys broader use in lung microbiome research.[6–9] Table 121-1 lists selected key elements in microbiome investigation relevant to this review.

SAMPLE TYPES

The human respiratory tract has been studied using a variety of techniques. Generally, the gold standard in evaluating the lower respiratory tract is bronchoalveolar lavage (BAL). Obtaining a BAL sample requires bronchoscopy and provides specimens from the small segmental airways and alveolar compartment. However, BAL samples a relatively large surface area of the lung and, in heterogeneous lung disease, likely samples both normal and diseased areas. An early concern in obtaining BAL for microbiome analysis was "carryover" from the upper airways during bronchoscopy. Studies have used sampling via protected brushes and other high-stringency methods to confirm that the taxa are authentically present in the lung and do not reflect procedural carryover from the upper respiratory tract.[10–12]

TABLE 121-1 Microbiome Terminology

- Microbiome: the community of microbes and their gene content in an environmental niche
- Microbiota: the community of microbes in a given niche
- Mycobiome: the fungal microbiome
- Virome: the viral microbiome
- 16S rRNA: gene commonly used for targeted sequence analysis of bacteria and archaea
- 18S rRNA: gene commonly used for targeted sequence analysis of fungi
- Internal transcribed spacer (ITS) sequence: region in the rRNA locus commonly used for targeted sequence analysis of fungi
- Operational taxonomic unit: closely related sequences grouped together to represent a unit of bacteria ("taxon")—for example, 16S sequences clusters sharing 97% sequence identity
- Amplicon sequence variant (ASV): amplified 16S sequences that are binned together based on 100% identity
- Richness: number of different taxa present in a community
- Evenness: equality of distribution among taxa in a community
- Alpha diversity: the within-sample diversity that incorporates both richness and evenness
- Beta diversity: compositional differences between two or more microbial communities
- Dysbiosis: deviation from the normal, optimal, or healthy microbiome in a particular niche
- Relative abundance: proportion of sequences that align with a taxon within a sample; this does not necessarily represent the absolute abundance of that bacteria in a sample
- Shotgun sequencing: sequencing of the entire DNA content in a sample based on generation of random fragments and alignment of these fragments to a database to generate annotations to specific bacteria, fungi, or viruses and their respective genes
- Metagenomics: the study of genetic material recovered directly from an environmental niche without ex vivo culture or perturbation
- Metatranscriptomics: analysis of all the RNA (typically messenger RNA) of a sample to understand functional capacity
- Taxon (plural, taxa): a grouping of microbes at a taxonomic level such as family, genus, or species

Figure 121-1 Overview of microbiome study methodology. There are multiple phases in the execution of a microbiome study. Those in bold need particular attention in the conduct and evaluation of lung microbiome studies, given the unique features of this niche: low-biomass status, dynamic nature, and close relation to the upper respiratory tract.

Sputum samples are commonly used, noninvasively obtained, and readily available. These are attractive features for microbiome analysis in the nonintubated patient. Challenges include quality control of the sample and the fact that sputum is inevitably an admixture of upper and lower airway microbiota. Furthermore, the proportions of these two compartments is dynamic and difficult to predict.[13] Interestingly, in more severe disease, sputum may more accurately reflect the microbiota of the lower airways.[14]

Other sampling methods used to study the respiratory tract include tissue samples,[15] tracheal aspirates,[16] induced sputum,[13] and exhaled breath condensates.[17] Each has its advantages and shortcomings and, importantly, tends to produce results that are not completely overlapping.[18–20] Therefore, in interpreting respiratory tract microbiome studies, it is imperative to note the sampling method. Combining analysis of the lower respiratory tract microbiome with samples or swabs from the upper airway (oropharynx or nasopharynx) and/or gastrointestinal tract is a powerful tool in placing complex, within-subject dynamics and host–microbiome interactions in proper context.

MICROBIOME ANALYSIS

Sequencing of whole microbial communities yields rich and dense data. To date, there is no consensus on the best pipeline or analytical tools,[18] but there are emerging best practices.[20] After careful quality control and filtering of data (which is beyond the scope of this chapter),[21] the basic output is a table of the relative abundances of each microbial taxa in a given sample. Key features of microbiome data that require careful statistical approaches are as follows: (1) the data are *wide*, with many more microbial features than samples in a typical study, (2) the data are *sparse*, with most taxa having an abundance of zero in a given sample,[22] and (3) the data are *compositional*, in which all the relative abundances of a microbial taxon sum to one in a sample.[23] The lung is a low-biomass system, and therefore extra care must be taken in assessing the quality of the data sequencing. In addition, concerted effort is needed to tease apart the relatively smaller signal from the inevitable noise introduced by sampling contamination and bacterial sequence contamination from instruments and reagents.[20,24]

After data processing, one important data output is a summary of the diversity of the complex communities. The approach is an ecologic one, and methods initially developed to understand diversity of outdoor environs[25] have been adapted for human microbial study.[26] One elemental metric is known as *alpha diversity*. This is a within-sample measurement of how many distinct microbes are present and how evenly are they distributed. *Richness* is the measure of the number of taxa per sample; other indices, such as the *Shannon index*, account for both richness and evenness.[27]

Alpha diversity provides an overall portrait of the health of a community; generally, higher diversity is considered healthier. There are notable exceptions reported in the literature, such as in the vaginal microbiome[28] and the bronchial microbiome in asthma.[29] *Beta diversity* is the measure of the difference in composition between two samples; a greater difference means a more distinct microbiome. Two of the most commonly used metrics of diversity are the Bray-Curtis dissimilarity and UniFrac distance measures.[30] An extension of beta diversity analysis is creation of *clusters* of similar samples to create "microbiome types," generally through machine learning clustering methods."[31–33]

In addition to microbial diversity, *abundance of bacteria* is an important metric. This measure has traditionally been assessed using 16S rRNA qPCR to determine the bacterial biomass. More recently, *droplet digital PCR*, which has much higher sensitivity, has been used to quantify bacterial burden in a sample.[34] This technique holds great promise, as multiple studies have linked biomass to outcomes in idiopathic pulmonary fibrosis[35] and lung transplantation.[36]

Microbial function can be either inferred or measured directly. A common computational approach uses *imputed metagenomics*[37] to infer the functional potential of the microbes discovered in a given community based on marker gene sequencing. More directly, the bacterial DNA genes can be quantitated during shotgun metagenomic sequencing, and the transcribed RNA measured using metatranscriptomic study.[21,38] These study types are computationally difficult, and the sequencing is costly.

In addition to measuring functional potential of a microbial community through DNA and RNA sequencing, the downstream intermediaries of the host interaction, namely, metabolites and proteins, constitute an active area of investigation. While complex, these approaches hold the promise of identifying networks of interaction that mediate disease.[31,39,40] One such study identified that metatranscriptomics of BAL best predicted short-chain fatty acid (SCFA) production, as measured by mass spectrometry, and captured dynamic microbial SCFA metabolism using a murine model.[38]

THE HEALTHY LUNG MICROBIOME

Below we consider important attributes of the healthy lung microbiome.

■ The Normal Lung Microbiome: Scant, Dynamic, and Largely Derived from the Upper Respiratory Tract

Traditionally, healthy lungs were thought to be sterile, but work in the last decade has definitively disproved that notion. Healthy lungs harbor low levels of bacteria—a finding based on molecular detection and, to a more limited extent, high-sensitivity culture.[10,12] Given that the lung is contiguous with the microbe-rich upper respiratory tract, coupled with the fact that we inhale multiple liters of air per minute from the nonsterile external environment, this is, perhaps, not surprising. Applying rigorous approaches, we now know healthy lung composition significantly overlaps with the upper respiratory tract and glottic region.[10] The most prevalent taxa in the healthy lung are from the Firmicutes and Bacteroidetes phyla, a finding that has been remarkably consistent across studies and geographic sites.[10,11] The most common genera within these phyla are *Prevotella*, *Streptococcus*, and *Veillonella*.

These findings indicate that the main source of lung microbes is microaspiration from the upper respiratory tract,[11,41] an event that is known to occur in all healthy people.[12] In the normal lung, the bacterial populations are transient because of efficient clearance by mechanical and innate immune defenses.[42] Aspirated bacteria immediately encounter airway mucus and mucociliary action, alveolar macrophages and neutrophils, and the airway epithelium as first lines of defense against bacterial colonization.[42] There are subtle regional differences within the lung and from upper respiratory communities, suggesting that differential clearance and/or local replication occur even in healthy people.[11]

An important limitation of 16S rRNA is its inability to distinguish live from dead bacteria. However, other methods have identified that a proportion of these lung-derived bacteria are viable and transcriptionally active.[43] These characteristics of the healthy lung microbiome as transient and dynamic stand in contrast to the higher-biomass, locally replicating, resident gut microbiome. Hence, vastly different ecologic forces are applied to the microbial communities of the two niches.[44]

■ The Lung Microbiome: Surveilled by the Immune System and a Regulator of Local Immune Tone

Despite the relatively low biomass and dynamic nature of the lung bacterial microbiome, it has important effects on the immune environment in the lung. In healthy humans, the presence of microbial sequences in the lung that mirror those in the oropharynx correlate with higher basal Th17 lymphocytes when compared with those whose lung bacteria cluster with control samples.[45] This suggests that entry of upper respiratory–derived microbiota regulates immunity in the lung.

At the same time, it is well established that the gut microbiome, with an exponentially higher biomass, determines, in part, the systemic immune "tone" that may impact the local lung immune milieu—the so-called gut–lung axis.[46] A murine study found that while both local lung and gut microbiota influenced lung immune profiles, the lung microbiome was the much stronger influence.[47] Hence, both the lung–lung axis and gut–lung axis seem to contribute to the lung immune setpoint in health.

THE LUNG VIROME AND MYCOBIOME

The viral and fungal components of the lung microbiome are less well studied than the bacterial microbiome. Apart from acute infection with community-acquired viruses, sequence-based analysis has identified Anelloviridae as the most common and abundant component of the lung virome, along with bacteriophages; more variable has been the detection of other eukaryotic viruses, including Herpesviruses and Papillomaviruses.[48,49] Anelloviridae are small, single-stranded, DNA circular-genome viruses found in blood and many tissues. Their prevalence is nearly 100% in humans, although they have not been associated with disease.[50]

Fungal constituents of the microbiome in health also are understudied and present unique challenges.[6,10,49,51–54] In addition to upper respiratory tract and background contamination with fungi, many respiratory samples have very low fungal biomass and low numbers of fungal taxa.[55] In addition, fungal cell walls are difficult to lyse, and there are biases in 18S and ITS primers. Finally, nonstandardized nomenclature and poor annotation of fungal databases complicate classification.[49] Limited small studies in healthy lungs show low fungal biomass and interindividual heterogeneity; fungi from the Ascomycota phylum are most common, followed by Basidiomycota. The main genera are *Candida*, *Saccharomyces*, *Penicillium*, *Cladosporium*, and, occasionally, other environmental taxa; *Aspergillus* and *Pneumocystis* are inconsistently identified at low levels in health.

GUT–LUNG AND ORAL–LUNG AXES

Evidence has emerged that the oropharynx and gastrointestinal tract influence the lung microbiome. The influence arises from direct effects from anatomic contiguity of the oropharynx and the airways[10,45,56–58] and, potentially, from gut–lung translocation of bacteria (mostly described in the context of critical illness[59] and severe immunosuppression[60]). Indirect influence arises through a shaping of the inflammatory milieu and host response in the lung.[61] Studies have revealed that microaspiration is likely the predominant source of lung bacteria.[12]

In children, the oropharyngeal microbiome overlaps more with the lung in those with impaired swallowing mechanisms; more overlap is seen in the lung and gastric aspirates in those children with intact swallowing mechanisms.[62] Interestingly, horses and other quadrupeds likely have a relatively greater contribution from the nasopharynx than the oropharynx because of the attenuated effect of gravity.[63] Therefore, the oropharynx and supraglottic space are important to understanding the sources of lung communities. This is clearly important in health when lung microbiome communities constitute low biomass and are dynamic. The extent to which this is true in advanced lung disorders, in which there is more local proliferation in the lung, remains to be determined.

The gut microbiome has been shown to regulate systemic immunity in multiple ways.[64,65] The high biomass of gut microbiota interacts with the gut mucosal immune system, and these numerous, dynamic interactions influence systemic immune tone.[66] In addition, the gut microbiome is a source of metabolites that enter the systemic circulation and influence distant targets.[67–69] Finally, in critical illness and advanced HIV the gut barrier function is impaired, and gut bacteria and/or their products may access the circulation.[70–72] The extent to which this impacts lung microbiome function is an open area of investigation. Therefore, in general, it is important to consider the lung microbiome not in isolation, but in conjunction with other mucosal niches.

DISEASE ASSOCIATIONS

Table 121-2 includes selected findings regarding the associations between the lung microbiome and common lung diseases. In this section we highlight two clinical states: interstitial lung disease and post–lung transplantation. These scenarios represent the diversity of microbiome investigations and highlight the promises and challenges of determining the role of the lung microbiome.

■ Microbiome in Interstitial Lung Disease

Significant radiographic, pathologic, and clinical heterogeneity exists across the numerous forms of interstitial lung disease. Microbiome analysis is an ideal tool to actively assess potential differential etiologies and markers of risk for disease progression. Additionally, microbiome assessment allows for potential development of novel therapeutic modalities. Two disease states highlight the innovative role of microbiome analysis: sarcoidosis and idiopathic pulmonary fibrosis.

Microbiome in Sarcoidosis

Given the complicated interplay of genetic susceptibility and environmental exposure, combined with the central pathologic finding of granulomas in sarcoidosis, significant efforts have been aimed at identifying an underlying infectious etiology or microbial biomarker for aiding in the diagnosis and prognosis for sarcoidosis.

Whole blood gene expression studies utilizing machine learning to identify patterns demonstrate significant overlap with tuberculosis gene expression signatures.[73]

A 2013 meta-analysis identified a significantly increased risk of sarcoidosis associated with *Propionibacterium acnes* identification.[74]

Small, single-center studies have focused on further assessing the causal role of the microbiome in sarcoidosis. A study comparing 31 patients with sarcoidosis and 19 controls with non-sarcoidosis-related ILD demonstrated no difference in microbial richness or alpha diversity and no difference in specific operational taxonomic unit composition between the two groups.[75] Notably, 20% of the identified operational taxonomic units could not be assigned to a specific genus, limiting the studies' capacity to potentially identify a sarcoidosis-associated organism.

A study of 93 patients compared those with sarcoidosis to controls using environmental samples to assess the microbiome, mycobiome, and virome of lymph nodes, BAL, and spleen specimens, as well as Kveim reagent, to assess for lineages enriched in sarcoidosis.[6] While there were tissue-specific enriched organisms identified, including *Cladosporiaceae* fungal isolates in lymph node tissue and *Aspergillus* in BAL, no organism was shared across tissue types after false discovery rate correction. This study also highlighted the importance of assessing environmental admixture when assessing low microbial biomass sites.

A study of 19 patients with ILD, including 10 with sarcoidosis, did not identify a specific microbial signature for sarcoidosis, although the study was limited by small sample size.[76]

When excluding oral taxa, a study of 21 patients with sarcoidosis identified *Erythrobacteraceae*, a group of organisms without known human disease pathology, to be enriched in patients with sarcoidosis.[77]

Accumulating data, combined with ongoing interest in an unknown microbial trigger for sarcoidosis, led to the design and implementation of the National Institutes of Health–funded Genomic Research in Alpha-1 Antitrypsin Deficiency and Sarcoidosis (GRADS) study, the primary objective of which is identification of patterns in the lung microbiome associated with sarcoidosis severity and disease phenotypes.[78] With a planned enrollment of 400 subjects, the study has the potential to greatly improve our understanding of the complex interplay between the microbiome and sarcoidosis, and the sample size may enable identification of novel sarcoidosis-related or sarcoidosis-specific organisms.

Microbiome in Idiopathic Pulmonary Fibrosis

The impact of lung microorganisms on idiopathic pulmonary fibrosis (IPF) has been highlighted over the last several years in multiple clinical trials and observational studies.[79,80] The role of the lower respiratory tract microbiome in pathogenesis of IPF can be considered with regard to several disease phases, including early disease, acute exacerbation of IPF (AE-IPF), and late, advanced disease.

Clear differences exist in the microbiome of patients with IPF compared with healthy controls. Indirect evidence for a role for microbial populations includes a statistically significant increased risk of death associated with immunosuppression, as well as a decrease in mortality and improvement in quality of life among patients treated with trimethoprim-sulfamethoxazole (TMP-SMX).[81,82] While not statistically significant in a study with limited overall sample size, bacterial diversity, as measured by richness and Shannon diversity, was lower in patients with idiopathic interstitial pneumonia compared with patients with other lung diseases or healthy controls.[83] An early study evaluating the culture-independent composition of the lower respiratory tract of IPF and other patients with ILD identified numerous, noncultured organisms, including *Actinobacterium*, *Neisseria*, *Haemophilus influenzae, Streptococcus*, and *Moraxella,* (predominantly components of oral flora).[84]

Multiple studies have implicated specific organisms or changes in the microbiota with acute exacerbations of IPF. A case control study of 20 patients with AE-IPF and 15 stable patients with IPF revealed (1) increased total microbial load in the BAL of patients with AE-IPF; (2) higher relative abundance of *Campylobacter* and *Stenotrophomonas* spp. in those with AE-IPF; and (3) lower relative abundance of *Veillonella* spp.[85]

Using a subgroup of patients from the prospective observational cohort study COMET-IPF, investigators identified *operational taxonomic unit*s matching *Staphylococcus* and *Streptococcus* to be strongly associated with rapid disease progression.[86] Relative threshold levels of 3.9% for *Streptococcus* and 1.8% for *Staphylococcus* also strongly correlated with differential survival.

A study using TGF-β1–overexpressing mice demonstrated increased growth of *Staphylococcus nepalensis* and identified a novel proapoptotic peptide, corisin, that induced lung epithelial cell apoptosis.[87] Furthermore, inhibition of corisin with polyclonal anti-corisin antibody prevented apoptosis; instillation of either corisin or *S. nepalensis* exacerbated fibrotic disease in the mouse model. Furthermore, corisin levels are significantly elevated in the BAL fluid of patients with AE-IPF compared to healthy controls.[87] These studies highlight the potential utility of microbiome analysis for

TABLE 121-2 Select Lung Microbiome Disease Associations

Disease State	Microbiome Associations	References
Lung cancer	Increased Proteobacteria in lung cancer.	Greathouse et al., 2018[125]
	Acidovorax identified by fluorescent in situ hybridization and 16S sequencing (significant increase in squamous cell carcinoma cases with TP53 mutations).	
	Elevated Proteobacteria in squamous cell carcinoma compared to adenocarcinoma and increased diversity in BAL.	Gomes et al., 2019[126]
	PI3K pathway upregulated with oral taxa enrichment in airway brushes of cancer cases.	Tsay et al., 2018[127]
Cystic fibrosis	Ivacaftor significantly decreased bacterial burden and *P. aeruginosa* (but did not eradicate) burden and markers of inflammation.	Hisert et al., 2017[128]
	Lung function declines correlated with increase in potential pathogen dominance and decreased diversity over time.	Cuthbertson et al., 2020[129]
	Under 2 years of age, patients with CF have abundant *Streptococcus*; this becomes replaced with pathogens in older children and adults.	Zemanick et al., 2017[130]
Chronic obstructive pulmonary disease (COPD)	Neutrophilic endotype of COPD had a *Haemophilus*-predominant (clinically stable, high IL-1b, TNF-α) and balanced microbiome (clinically dynamic, elevated IL-17a) subgroups. Eosinophilic endotype had enrichment of nondominant taxa.	Wang et al., 2020[131]
	Longitudinal increases in *Moraxella* and *Actinobacillus* most strongly correlated with exacerbations.	
	Elevated *Staphylococcus* relative abundance and low alpha diversity increased risk of mortality when found after a hospitalization for an acute exacerbation of COPD.	Filho et al., 2019[132]
	Lung tissue microbiome in mild to moderate COPD found enrichment of nasal and oral taxa.	Pragman et al., 2018[133]
	More within subject similarity of bronchial and lung microbiome than between types across subjects.	
Asthma	Asthmatic subjects had higher diversity than healthy controls or those with atopy without asthma in protected bronchial brushings.	Durack et al., 2017[29]
	Baseline Streptococcaceae, Fusobacteriaceae, and Sphingomonadaceae predicted response to inhaled corticosteroids (ICS).	
	No significant differences in sputum microbiome in high- versus low-dose ICS asthma treatment. *H. parainfluenzae* enriched in high-dose fluticasone versus budesonide.	Martin et al., 2020[134]
	The bedroom environmental mycobiome and sputum mycobiome have significant overlap during asthma exacerbations and contain clinically significant fungi.	Vandenborght et al., 2020[135]
Acute respiratory distress syndrome (ARDS)	The lung becomes enriched with gut bacteria (Bacteroidetes) in ARDS, implicating translocation as a possible mechanism.	Dickson et al., 2016[59]
	Higher bacterial burden and composition with gut-associated bacteria on admission to the ICU in intubated patients predicted fewer ventilator-free days and ARDS.	Dickson et al., 2020[136]
	Mechanically ventilated patients with low alpha diversity and enrichment with potential pathogens and high inflammation, longer duration on mechanical ventilation, and lower 30-day survival.	Kitsios et al., 2020[137]
HIV-related pulmonary disease	*Tropheryma whipplei* is prevalent in the lungs of persons living with HIV (PLWH).	Lozupone et al., 2013[138]
	No difference in lung bacterial composition between PLWH and healthy controls in well-controlled and early disease.	Beck et al., 2015[139]
	In advanced HIV, there is a reduction over time of alpha diversity and differences in bacterial composition compared with non-HIV controls.	Twigg et al., 2016[140]
Lung infection	An integrated approach with metagenomic sequencing and transcriptomics was able to differentiate infectious versus noninfectious causes of respiratory failure.	Langelier et al., 2018[141]
	Oral taxa such as *Prevotella* may drive progression to active TB through production of short-chain fatty acids that activate anti-inflammatory regulatory T cells in the lung. These cells in turn reduce IL-17a and IFN-γ needed to control TB infection.	Segal et al., 2017[142]
	16S rRNA sequencing is less sensitive than culture in detecting nontuberculous mycobacteria (NTM). NTM culture–positive patients who were enriched in oral taxa had increased inflammatory biomarkers.	Sulaiman et al., 2018[13]
IPF	*Campylobacter* and *Stenotrophomonas* are associated with risk of acute exacerbation of IPF.	Molyneaux et al., 2017[85]
	Staphylococcus and *Streptococcus* are strongly associated with rapid disease progression in IPF.	Han et al., 2014[86]
	Murine model of IPF using TGF-β1 overexpression demonstrated *Staphylococcus nepalensis*—release of the proapoptotic peptide corisin resulted in progressive pulmonary fibrosis.	D'Alessandro-Gabazza et al., 2020[87]
Sarcoidosis	Erythrobacteraceae, a group of organisms without known human disease pathology, are enriched in patients with sarcoidosis.	Fukui et al., 2020[77]
	National Institutes of Health–funded Genomic Research in Alpha-1 Antitrypsin Deficiency and Sarcoidosis (GRADS) study is ongoing.	Moller et al., 2015[78]

identifying patients at risk for AE-IPF, although the lack of consistent findings across studies and among populations of patients with IPF and the small number of patients studied precludes generalization of results.

In a study utilizing explanted lung tissue samples from end-stage, transplanted patients with IPF, the total microbial load identified was indistinguishable from negative controls, indicating that the honeycombed portions of the lung with IPF contain no inherent microbiome.[15] A similar study of explanted lungs with advanced IPF demonstrated higher bacterial burden in the airways compared to lung parenchyma of patients with IPF.[88] Investigators identified a cluster of samples with high bacterial load, low alpha diversity, and increased typical airway organisms, including *Streptococcus*, *Veillonella*, or *Prevotella*. This cluster was also associated with higher rates of death, use of antibiotics, and incidence of AE-IPF.

Similar to the earlier indirect evidence for bacterial involvement in IPF, there is indirect evidence for a role for viral infection. Case reports and small, open-label trials of ganciclovir administration demonstrate stabilized lung function.[89,90] Multiple studies have implicated herpesviruses in the potential pathogenesis of IPF as well.[91]

The association of altered or different microbiomes or viromes with advanced IPF is also intriguing. However, as for associations with AE-IPF, correlations themselves are not evidence of causation; they require further investigation. For example, despite prior evidence that TMP-SMX improved IPF outcomes, a recent, randomized trial of 342 patients with IPF showed no difference in time to death, transplantation, or nonelective hospitalization compared with placebo.[92] At present, causative microbial organisms or obvious new novel targets for therapy based on non-culture-based identification remain elusive.

■ The Post–Lung Transplantation Microbiome

Below we consider the bacterial microbiome, the virome, and the mycobiome in lung transplant recipients.

Bacterial Microbiome

Multiple studies have revealed an elevated bacterial burden in lung transplant recipients compared with healthy controls, ranging from 15-fold to 1000-fold higher.[51,93–96] Across studies, a subset of posttransplant patients maintains a lung microbiome composition predominantly of oral-type flora,[51,94,96,97] while most have a marked decrease in alpha diversity accompanied by an outgrowth of specific taxa. Quantitative comparison of lung versus upper respiratory tract communities shows outgrowth in the lung of commensals and potential pathogens, such as *Pseudomonas*, *Enterobacteriaceae*, *Staphylococcus*, as well as anaerobes.[51]

In longitudinal studies, upper respiratory tract flora usually are the predominant taxa in the lung microbiome in the first year after transplant;[94,97] this profile is also seen after the first posttransplant year.[96,98] The most abundant phylum is Bacteroidetes, followed by Firmicutes, then Proteobacteria and Actinobacteria.[94,97] A smaller proportion of samples exhibit outgrowth of *Corynebacterium* and potential pathogens such as *Pseudomonas*, *Staphylococcus*, and *Stenotrophomonas*. In cystic fibrosis (CF), two main types of posttransplant lung bacterial communities have been described: one typical of oral bacteria (particularly *Streptococcus* and *Veillonella*) and one dominated by *Pseudomonas*.[98]

Thus, across studies, the posttransplant lung microbiome has a higher biomass and is dysbiotic (i.e., deviates from normal lung composition), but the specific nature of the dysbiosis tends to be patient-specific. In addition, variability based in space and time is noted. In transplant patients, differences have been reported between proximal and distal airway samples[99,100] and between native lungs and allografts in single lung transplant recipients.[95] This could result from regional differences in organism entry, clearance, or local replication. In addition, there are complex dynamics at the time of transplant and in the first posttransplant year. Early on, donor microbiota persists in some subjects post-transplant, while in others, it is rapidly replaced.[98,101] In CF, *Pseudomonas* strains derived from the transplant recipient populated the allograft within days.[102,103] After the first year, extensive change occurs over time in bacterial composition at lower taxonomic levels, although more stability is noted at higher taxonomic levels.[104] These considerations preclude broad generalizations about a homogenous, "posttransplant lung microbiome" composition. It is this very heterogeneity that suggests distinct outcomes may be linked to microbiome profiles.

The Bacterial Microbiome and Outcomes

Chronic lung allograft dysfunction (CLAD) is the chronic loss of allograft function and is the primary cause of late morbidity and mortality in lung transplantation.[105,106] Bronchiolitis obliterans syndrome (BOS), the more common obstructive form of CLAD, has had variable associations with the lung microbiome. An early study found that the presence of *Pseudomonas* species in CF subjects post-transplant appeared protective against BOS, particularly if the patient had *Pseudomonas* previously identified.[98] In contrast, enrichment with oral taxa increased the incidence of BOS. This did not hold true for non-CF subjects. Furthermore, decreased diversity over time within an individual increased the risk of BOS. These findings raise the hypothesis that the stability of the microbiome over time increases BOS risk.

Subsequent studies have reported different microbiome correlations with BOS. A small, uncontrolled study found enrichment of *Actinomyces* and Xanthomonadaceae in BOS.[104] Another found that Actinobacteria dominance (*Propionibacterium* and *Corynebacterium*) at 3 months post-transplant had lower rates of BOS, less inflammation in BAL, and lower rates of acute cellular rejection.[107] However, this association did not hold for later time points, suggesting a time-dependent association with outcomes. In an examination of topographic features of the posttransplant lung microbiome, microbial and inflammatory profiles differed in proximal and distal airways, and BOS was linked to specific taxa from three phyla (Proteobacteria, Bacteroidetes, Firmicutes) in distal, but not proximal, specimens.[100]

In summary, emerging data suggest a complex relationship between the lung transplant bacterial microbiome and BOS. Unraveling this complexity must account for temporal, spatial, and patient-specific factors. In addition, cross-kingdom interactions with the virome and mycobiome, as well as an integration with the multifaceted host response after lung transplantation, warrant further study.

The Virome and Mycobiome

Herpesviruses, particularly cytomegalovirus and herpes simplex virus, are important pathogens after lung transplantation and are targets of prophylactic antiviral regimens.[108] Community-acquired respiratory viruses, such as influenza, enteroviruses, and rhinoviruses, lead to acute morbidity and increased risk of later CLAD.[109–111] These viruses are typically identified using targeted PCR methods. While there is a burgeoning literature probing the human virome through sequence-based methods,[48,111–114] only a few have focused on the lung, and even fewer on lung transplantation.

The most abundant eukaryotic viruses in lung transplant BAL are of the Anelloviridae family—small circular DNA viruses (such as torque teno virus [TTV]).[48,111–114] Despite their prevalence and abundance, Anelloviridae effects on the host are not well understood. Altered peritransplantation dynamics of Anelloviridae have been associated with primary graft dysfunction,[113] in which subjects had smaller increases in Anelloviridae levels, suggesting that the robust immune activation may lead to both acute lung injury and inhibition of viral replication. Lung Anelloviridae levels remain elevated after transplant and correlate with the degree of bacterial dysbiosis, indicating interkingdom covariation.[48,112] The consequences of persistent Anelloviridae elevations and allograft/recipient virome intermixing remain to be determined.

Bacteriophages (or phages) are abundant in the lungs of transplant recipients, particularly phages that infect bacterial inhabitants of the human respiratory tract.[113] Phages can influence bacterial pathogenesis in the lung, particularly in CF.[115] Also, emerging data suggest that phages may directly interact with human cells and modulate innate immune function.[116] However, what role phages play post-transplantation is unknown. Phages have also garnered interest as treatments for multidrug-resistant bacterial infections, such as *Pseudomonas* and *Mycobacterium* species, including in lung transplant recipients.[117,118]

A limitation in interrogating the virome using deep sequencing is the incomplete nature of viral databases that do not identify many of the viral sequences—so-called viral dark matter. Recent contributions have chipped away at this dark matter. One such study identified a novel viral family termed Redondoviridae (named for their small, circular DNA genome).[119] Future studies are needed to determine what role these and other newly discovered members of the human virome have in lung health and disease.

Based on fungal culture, *Aspergillus* and *Candida* are commonly identified in lung samples after transplantation.[51,55] *Aspergillus* is associated with early anastomotic complications, as it grows in ischemic anastomotic tissue.[120] Several studies have linked *Aspergillus* infection or colonization to later CLAD,[121,122] although one large cohort study found no association.[123] Invasive *Candida* infections are common after lung transplantation and usually involve the bloodstream, pleural space, or surgical site.[108,124]

The first posttransplantation metagenomic analysis found that fungi were highly variable among patients in absolute quantity and composition.[51,55] *Candida* was the most prevalent taxon and, when abundant in the lung, was also abundant in the oropharynx. This contrasted with healthy controls, in whom *Candida* was prevalent in oral samples but scarce in lung. *Aspergillus* was seen in BAL, sometimes at high levels, while other subjects had *Cryptococcus* and environmental fungi. Additionally, there was significant interkingdom covariation between *Candida* and *Rothia*, *Streptococcus*, and *Veillonella*.[55]

CONCLUSION

Study of the lung microbiome is a relatively new and evolving field that applies advanced computational approaches to dissect host–microbe interactions. Advances in technology and analytical methods have illuminated our understanding of the complex microbial communities that inhabit the lung in health and disease—yet methodologic limitations and hurdles remain. Future lung microbiome research will attempt to overcome these barriers and advance our knowledge of host–microbe interactions increasingly from the lab to the bedside in the form of improved prognostic, diagnostic, and therapeutic capabilities.

CHAPTER 122

Approach to Pulmonary Infection in the Immunocompetent Host

Megan Rose Curtis
Tulip Ajit Jhaveri
Camille Nelson Kotton

OVERVIEW

Pneumonia is defined as inflammation of the pulmonary parenchyma caused by an infectious agent. In the fifth century BC, Hippocrates and his pupils first observed the cardinal symptoms of pneumonia: productive cough, fever, and dyspnea. He pioneered the use of auscultation, comparing the oscillations between the hemithoraces to diagnose lower respiratory tract infections.[1] Despite millennia of medical advances, pneumonia continues to cause significant morbidity and represents the leading cause of infection-related mortality worldwide.[2] Clinicians still rely primarily on history and physical examination when caring for a patient with suspected pneumonia. The clinical presentation of pneumonia is vastly heterogenous and may include fever or hypothermia; sweats; rigors (chills); pulmonary symptoms such as cough, sputum production, dyspnea, or pleurisy; and pulmonary lesions observed on radiographic examination. Nonspecific symptoms are common, including loss of appetite, fatigue, and confusion. The classic findings on physical examination include "crackles" or "rales"; however, the accuracy of clinical signs and symptoms alone have been shown to be ineffective in successfully diagnosing pneumonia.[3] Radiographs assist in identifying a pulmonary lesion; however, findings may be nonspecific. Because there are no diagnostic tests available to identify the microbiologic etiology immediately upon presentation (besides those for viral causes), initial antibiotic treatment is empiric and should be started as soon as pneumonia is suspected.

Management of pneumonia is complicated by changing epidemiology. Widespread administration of the conjugate pneumococcal vaccine has significantly decreased the incidence of pneumococcal pneumonia. Additionally, there has been increased recognition of viral pathogens as molecular diagnostic tests have become more advanced.[4] Viral pathogens may cause coinfections or precede a subsequent bacterial superinfection. Outbreaks of novel pathogens, such as SARS-CoV-2, pose a unique and unheralded layer of complexity to the microbiologic epidemiology of pneumonia. Despite an expanding array of antimicrobial options for treatment, none can be used empirically to treat all possible pathogens, and overuse of broad-spectrum antibiotics has led to increasing antimicrobial resistance.[5] Pneumonia represents an important and demanding clinical challenge. Successful management requires synthesis of epidemiologic, clinical, laboratory, microbiologic, and radiographic data, as well as swift clinical decision-making.

The purpose of this chapter is to assist the clinician at any step of the diagnostic and treatment algorithms when caring for a patient with suspected pulmonary infection. The first portion of the chapter provides broad guidance for initial patient evaluation and establishes a basic framework for clinical assessment; common viral and bacterial pathogens are emphasized (Table 122-1). The next portion focuses on diagnostics available to the clinician, including laboratory, radiographic, and microbiologic studies. The focus is on creating a framework to assist in guiding the workup and evaluating data as they become available. The last portion of the chapter explores the details of viral, atypical, fungal, and parasitic pneumonias.

THE ROLE OF HOST DEFENSES

The presence of pneumonia should be taken as evidence of an immune defect relative to the epidemiologic pressure of the microorganisms (Chapter 120). Organisms of high native virulence (due to adhesion properties, presence of invasive enzymes, motility characteristics, or intracellular presence) may cause infection with a small inoculum size in an immunologically normal host (Chapter 124). Organisms of low virulence should cause infection only if there is an immune or anatomic predisposition to infection or a high burden of organisms.[6] Microorganisms may reach the lungs via the airways, bloodstream, or lymphatics. Defects in specific components of the immune system (innate and acquired) predispose to specific types of infection, as shown in Table 122-2.

An important first step in the pathogenesis of many infections is colonization of the upper airway via adhesion of organisms to epithelial surfaces. These surfaces are normally protected by mechanical clearance of organisms from the nose or oropharynx, local production of complement and IgA, the presence of saliva, sloughing of epithelial cells, and bacterial interference by "normal flora." Changes in these surfaces (diminished IgA secretion, changes in production of adhesins or fibronectin, and altered lectin binding) predispose to adhesion of microorganisms. Organisms carrying enzymes that can degrade IgA exotoxins, adhesion proteins, or pili more readily colonize the respiratory epithelium. Mucociliary clearance may be disrupted by cigarette smoking or prior infections with viruses, *Haemophilus influenzae*, or *Mycoplasma pneumoniae*.

Aspiration may result from altered glottic closure (e.g., due to neurologic injury, sleep apnea, airway intubation, alcohol consumption, or administration of anesthesia). Once bacteria or viruses traverse the glottis, most are small enough (<2 μm) to reach the alveoli, unless impeded by alveolar lining fluid containing surfactant, IgG, complement, and other proteins. Surfactant includes a variety of components that serve to activate alveolar macrophage and neutrophil functions and may serve as an opsonin (e.g., SP-A and SP-D) for many organisms. Organisms surviving the upper airway defenses are subsequently addressed by the cellular components of the lower airways, including T and B lymphocytes, macrophages, and dendritic cells.

Pulmonary defense mechanisms are also disrupted by systemic infections (including sepsis), hyperglycemia and diabetes, acidoses, hypoxemia, pulmonary edema, malnutrition, uremia, age, and acute respiratory distress syndrome (ARDS). Endotoxin and lipopolysaccharide diminish clearance of bacteria from the lungs. Viral infections may diminish neutrophil and macrophage functions, including phagocytosis, chemotaxis, and oxidative metabolism.

The microbiome of the lung may play an important role in pneumonia pathogenesis (Chapter 121). Innovations in culture-independent microbial identification has highlighted the presence of diverse communities of organisms within the lung parenchyma, traditionally thought to be "sterile."[7] Microbes in the alveoli may exert an effect through modulating the host immune response or directly by overgrowth of the lung parenchyma. Dysbiosis has been identified in obstructive pulmonary disease, idiopathic pulmonary fibrosis, cystic fibrosis, and bronchiectasis, all of which are risk factors for development of pneumonia.[8] More research is needed to better understand the role of the microbiome in pneumonia, as little is known about the interaction between the host immune system and microbes, including viruses, fungi, and bacteria.

TABLE 122-1 Routine Evaluation of Patients with Suspected Pneumonia

History	
Age	
Community (respiratory viruses, antimicrobial resistance) vs. hospital (ventilator)	
Pace of onset, dyspnea	
Recent infections (post–viral pneumonia, endocarditis, aspiration)	
Recent hospitalization or exposure to medical facilities (extended care)	
Underlying conditions (mental status, immunity, cardiopulmonary, medications)	
Exposures (illness, children, institutions, animals, gardens, travel)	
Antimicrobial therapies, home infusion therapy, vaccinations	
Duration of hospitalization or endotracheal intubation	
Physical Examination	
Laboratory	
Complete blood count with differential counts	
Electrolytes, liver function tests, BUN, creatinine	
HIV	
Radiology	
PA and lateral chest radiograph (depending on host and severity of illness)	
Consider: Chest CT with contrast, echocardiogram, thoracentesis, rarely biopsy	
Microbiology *(adapted to clinical setting and severity of illness)*	
Gram stain and culture	All typical bacteria—*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, *S. aureus*, enteric Gram-negative bacilli
Blood cultures (two sets)	All typical bacteria, some fungi and mycobacteria
Acid-fast smear and culture	*M. tuberculosis*, atypical mycobacteria, aerobic actinomycetes such as *Nocardia*
Fungal wet mount and culture	Molds (*Aspergillus* and mucormycosis), endemic mycotic agents (*Histoplasma*, *Blastomyces*, and *Coccidioides*)
Direct fluorescent antibody	*Pneumocystis*, *Legionella*, pertussis, and influenza and other respiratory viruses
Antigens	
–Bacterial	Pneumococcal urinary antigen, *Legionella* urinary antigen
–Viral	Influenza, SARS-CoV-2, RSV, parainfluenza, adenovirus, metapneumovirus
–Fungal	*Cryptococcus* serum antigen, *Blastomyces* urine antigen, *Histoplasma* urinary antigen, BDG, galactomannan
Molecular assays (NAAT)

–Mycobacteria	*M. tuberculosis,* nontuberculous mycobacteria
Serologic tests	
–Bacterial	*Mycoplasma*, *Chlamydophila*, Q fever, tularemia, anthrax
–Viral	Influenza, SARS-CoV-2, RSV, adenoviruses, parainfluenza
–Fungal	*Histoplasma*, *Coccidioides*, sporotrichosis, toxoplasmosis

BUN, blood urea nitrogen; HIV, human immunodeficiency virus; PA, posteroanterior; CT, computerized tomography; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; RSV, respiratory syncytial virus; BDG, 1,3-B-D-glucan; NAAT, nucleic acid amplification test; HSV, herpes simplex virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus

GENERAL GUIDELINES IN EVALUATING PATIENTS WITH PNEUMONIA OR OTHER RESPIRATORY INFECTIONS

A patient with pulmonary infection often presents in an ambulatory setting. The clinician's goal is to distinguish infectious from noninfectious processes, to initiate appropriate antimicrobial therapy quickly, and to define the microbiology. Achieving these goals is crucial to reduce unnecessary exposures to antimicrobial agents and to provide optimal care.

Evaluation of the patient with possible pneumonia depends on a series of questions that provide clues that guide the workup and inform selection of empiric antimicrobial agents. Broadly, the evaluation includes assessing disease severity, identifying risk factors for drug-resistant organisms, and appreciating comorbidities or underlying immunosuppression that confer increased risk of poor outcome.

Frequently, pneumonia is divided into categories that *may* reflect the epidemiology of the process and possible causative organisms (Table 122-3): aspiration pneumonia, lung abscess (Chapter 127), community-acquired pneumonia (CAP) (Chapter 128), nosocomial pneumonia (Chapter 129), the immunocompromised host (Chapter 123), and atypical pneumonia. These categories have been employed historically when choosing an empiric antibiotic. In the United States, recent Infectious Diseases Society of America/American Thoracic Society (IDSA/ATS) Guidelines for Diagnosis and Treatment of CAP suggest that local epidemiologic data may be more useful than these categories when choosing antibiotics[9] (Chapter 125).

Initial antimicrobial therapies should be considered as therapeutic trials and given adequate time to demonstrate effectiveness; they should be subject to revision if ineffective. Subsequently obtained

TABLE 122-2 Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric Gram-negative, *Pseudomonas*, *S. aureus*, *S. epidermidis*, streptococci, *Aspergillus*, *Candida*, and other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin disease, trauma (burns), lazy leukocyte syndrome, CT disease	*S. aureus*, *Candida*, streptococci
Neutrophil killing	CGD, myeloperoxidase deficiency	*S. aureus*, *E. coli*, *Candida*, *Aspergillus*
T-cell defects	AIDS, congenital causes e.g., DiGeorge (22q11.2 deletion) syndrome, autosomal dominant hyperimmunoglobin E/Job syndrome, and IL-12 receptor deficiency, lymphoma, sarcoidosis, viral infection, CT disease, organ transplants, steroids	Intracellular bacteria (*Legionella*, *Listeria*, mycobacteria), HSV, VZV, CMV, EBV, parasites (*Strongyloides*, *Toxoplasma*), fungi (*P. jirovecii*, *Candida*, *Cryptococcus*)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, ALL	*S. pneumoniae*, *H. influenzae*, *Salmonella* and *Campylobacter* spp., *Giardia lamblia*
Splenectomy	Surgery, sickle cell, cirrhosis	*S. pneumoniae*, *H. influenzae*, *Salmonella* spp., *Capnocytophaga*
Complement	Congenital/acquired defects	*S. aureus*, *Neisseria* spp., *H. influenzae*, *S. pneumoniae*
Anatomic	IV/Foley catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

AIDS, acquired immunodeficiency syndrome; ALL, acute lymphocytic leukemia; CGD, chronic granulomatous disease; CT, connective tissue disease; IV, intravenous.

microbiologic data provide the basis for adjusting antimicrobial therapy.

The clinician should pose a series of questions when caring for a patient with suspected pneumonia.

Is the process life-threatening and does the patient have risk factors for severe disease? Related questions are as follows: What is the rate of progression of the process? Is it rapidly progressive or gradual? Does this patient meet criteria for severe pneumonia? Does the patient have chronic heart, lung, liver, or kidney disease? Does the patient have diabetes mellitus, alcoholism, malignancy, asplenia, or underlying immunodeficiency? Table 122-4 highlights key risk factors for severe disease. Could the process be underestimated based on the absence of normal inflammatory responses (see Section 3: Lung Immunology)?

Which pathogens are most likely to be causing disease? In the past, it was helpful to resort to clinical categories of infections: community-acquired, nosocomial (hospital-acquired, ventilator-associated, acquired in a healthcare facility), or pneumonia in the immunocompromised patient. Such groupings have been used to provide a guide to empiric therapy while evaluation is underway. Additionally, it is important to understand the incidence of HIV, pattern of respiratory viral infections, and prevalence of antimicrobial-resistant organisms (e.g., *Pseudomonas aeruginosa*,

TABLE 122-3 Categorization of Pneumonia by Clinical Setting

Community-acquired pneumonia
- Typical (i.e., classic) pneumonia
- Atypical pneumonia
- Aspiration pneumonia
- Pulmonary abscess and empyema

Nosocomial pneumonia
- Hospital-acquired pneumonia (HAP)
- Ventilator-associated pneumonia (VAP)

Pneumonia in immunocompromised hosts
- Immunoglobulin and complement deficiencies
- Granulocyte dysfunction or deficiency (cyclic neutropenia, chronic granulomatous disease, leukocyte adhesion defects, myeloperoxidase, or G6PD deficiency)
- Innate immune defects (NK deficiency, defects of interleukin/interferon-γ pathways, pattern recognition receptor pathway defects)
- Cellular and combined immune deficiencies
  - Neoplastic disease (notably hematopoietic malignancy and therapies)
  - Solid-organ and hematopoietic transplant recipients
  - Untreated HIV infection
  - Immune reconstitution syndromes (IRIS)
  - SCID and congenital deficiencies
  - Autoimmune and connective tissue disorders
  - Other immunocompromised patients

Cystic fibrosis and anatomic disorders (bronchopulmonary sequestration, tracheomalacia, or bronchomalacia)

TABLE 122-4 Underlying Conditions Contributing to Adverse Outcomes from Pneumonia

- Alcohol consumption
- Increasing age
- Leukopenia
- Congestive heart failure
- Coronary artery disease
- Diabetes mellitus
- Immune compromise
- Neurologic disease
- Active malignancy
- Clinical signs including dyspnea/tachypnea, hypothermia, chills, hypotension, confusion or altered mental status
- Laboratory tests: hyponatremia, hyperglycemia, azotemia, hypoalbuminemia, liver function test abnormalities
- Radiographic infiltrates and pleural effusions, postobstructive pneumonia
- Microbiology: Gram-negative bacilli, *S. aureus*, mixed flora (aspiration), bacteremia

Staphylococcus aureus) in the community or institution. If available, clinicians should consult their local antibiogram. Dual infections are common (e.g., viral plus bacterial), and initial therapy must be directed at both common bacterial and "atypical" pathogens (i.e., *Mycoplasma*, *Chlamydophila*, and *Legionella* species) (Chapter 125). Inquiry about exposures to specific pathogens also is important, as is asking about prior residence in, or travel to, a region endemic for TB (Chapter 130). Knowledge of whether the patient ever presented with methicillin-resistant *S. aureus* (MRSA) or pseudomonal infection is important,[10,11] as is a history of the patient being previously hospitalized or having received parenteral antibiotics.

What are the gross radiologic features of the pulmonary process? Broad categories include frank pneumonia, with or without sputum production; focal infiltrates; lung abscess; chronic cavitary lesions; bronchiectasis; and miliary lesions. These distinctions can be helpful in diagnosing pneumonia; however, findings may be nonspecific. As a corollary, since pulmonary infections are occasionally generated by the hematogenous, rather than bronchogenic, route, possible extrapulmonary processes in the pathogenesis of pulmonary infection must be considered.

For ambulatory patients, does the patient need to be admitted to the hospital for management? Important determinants include whether the patient has social support in the community, whether he or she can manage oral medications, other therapies, and follow-up visits from home. Also to be considered are the need for supplemental oxygen, assisted ventilation, surgery, blood products, monitoring, or isolation.

CLINICAL EVALUATION

Pulmonary infections are often included in the differential diagnosis for a patient presenting with respiratory complaints.[12] Symptoms commonly associated with pneumonia include fever, cough, sputum production, dyspnea, and chest pain. Gastrointestinal symptoms, including abdominal pain and diarrhea, may be noted as well. The clinician should assess for evidence of alternative diagnoses and conduct a thorough medical history. For example, orthopnea and lower extremity edema may suggest congestive heart failure, while a history of malignancy may predispose toward pulmonary embolism, and a recent bout of vomiting or loss of consciousness (e.g., due to a cerebrovascular accident, seizure, or administration of anesthesia) may implicate aspiration pneumonitis rather than true infection.

Epidemiologic history is crucial and should include recent travel, contacts, exposures, history of vaccination, prior infections, and hospitalizations (Table 122-5). Treatment should be reserved for those patients for whom there is a reasonable suspicion of infection or who are seriously ill. Even the most thorough history may not help distinguish an infectious versus noninfectious process; antibiotics are frequently initiated empirically while additional workup is underway. Consideration of the epidemiology is crucial when evaluating a patient with suspected pneumonia.

■ Epidemiology

Streptococcus pneumoniae has long been considered the most common bacterial etiology of CAP, accounting for about 80% of cases before the advent of antibiotics.[13] However, the frequency with which *S. pneumoniae* is identified as the etiologic agent of CAP has been gradually declining. In the United States, *S. pneumoniae* has been isolated in 5% to 15% of cases.[4,14] Globally, *S. pneumoniae* accounts for an estimated 27% of cases.[15] In addition to *S. pneumoniae*, *Haemophilus influenzae*, *Legionella pneumophila*, *Moraxella catarrhalis*, *Mycoplasma pneumoniae*, *Staphylococcus*

TABLE 122-5 Epidemiologic Exposures Associated with Pneumonia

Pathogen	Epidemiology
Anthrax	Bioterrorism, animals, hides, raw wool, goat hair
Brucella sp.	Domestic animals, unpasteurized dairy products, abattoir, veterinarian
Chlamydophila psittaci	Birds: parrots, budgerigars, cockatoos, pigeons, turkeys
Coxiella burnetii (Q fever)	Goats, sheep, cattle, domestic animals (feces, amnionic fluid, placenta, milk)
Legionella	Contaminated aerosols, pooled water
Leptospirosis	Rodents, animals, water contaminated by animal urine
Melioidosis	West Indies, Australia, Southeast Asia, South Central America
Pasteurella multocida	Dogs, cats
Neisseria meningitidis *Mycoplasma pneumoniae*	Close living quarters such as university dormitories
Plague *(Yersinia pestis)*	Bioterrorism, squirrels, chipmunks, rabbits, prairie dogs, rats
Rhodococcus	Horses, soil, farms
Tularemia	Rabbits, squirrels, foxes, horses, soil, farms, bites from infected flies or ticks
Hantavirus	Rodent droppings/urine (predominantly in Southwestern United States, virtually all states)
SARS, avian influenza	Southern China
Middle Eastern respiratory syndrome (MERS): Coronavirus	Endemic regions (Saudi Arabia)
Coccidioidomycosis	Southwest United States
*Cryptococcus neoformans (*including var. grubii*)*	Birds (pigeons), caves, bats
Cryptococcus gattii	Eucalyptus trees
Histoplasmosis	Bird/bat droppings, endemic in central and eastern United States and Central America; also found in parts of South America, Africa, Asia, and Australia regions
Paracoccidioides	South America (Brazil)

aureus, and gram-negative bacilli account for a substantial portion of other bacterial pneumonias.

In recent studies, *S. pneumoniae* has been replaced as the most common cause of CAP by viruses and a broad array of bacteria. The Etiology of Pneumonia in the Community (EPIC) study was a large epidemiologic study undertaken by the U.S. Centers for Disease Control and Prevention to detect presence of pathogens in patients hospitalized with pneumonia in the United States. A virus was isolated in 27% of adults with radiographically confirmed cases of pneumonia. Bacterial pathogens were identified in 11% of patients, and *S. pneumoniae* accounted for only 5% of cases.[4] Similar findings were reported from a study identifying respiratory pathogens in more than 323 patients from the United Kingdom. This analysis identified viruses in 30% of patients. *S. pneumoniae* was isolated in only 5% of participants.[16] In both studies, rhinovirus, influenza A/B, parainfluenza virus, human metapneumovirus, respiratory syncytial virus (RSV), adenovirus, and endemic coronaviruses were the most commonly identified viral pathogens.[4,16] The decreasing incidence of *S. pneumoniae* likely reflects identification, using advanced techniques, of other organisms not identified in earlier studies, a reduction in the detection of the *S. pneumoniae* due to successful empiric therapy, and shifts in "community flora" through use of antimicrobial therapies. Reductions in smoking (a known risk factor for pneumococcal pneumonia), herd immunity through mass immunization of children with the pneumococcal conjugate vaccine, and recommendations for vaccination of adults at older age also are thought to play key roles in this epidemiologic shift.

Specific pathogens are associated with certain special populations or predisposing conditions. Hospitalized patients are at risk of *S. aureus*, *Klebsiella*, *Enterobacter*, and *E. coli*. *Acinetobacter*, *Stenotrophomonas*, and *Pseudomonas* are found in highest frequency among patients who are mechanically ventilated.[17] Age is an important epidemiologic factor. Gram-negative bacterial pneumonias are seen more frequently in older patients, whereas younger patients are more likely to present with pneumonia due to *M. pneumoniae*.[12] Nontypeable *H. influenzae* is seen in older adults, particularly those with underlying structural lung disease, such as chronic obstructive pulmonary disease (COPD) and cystic fibrosis. Pneumonia due to *Pseudomonas aeruginosa*, *Stenotrophomonas* spp., *Burkholderia* spp., *Achromobacter xylosoxidans*, and atypical mycobacteria are common among patients with cystic fibrosis (Chapter 123). HIV has been shown to be a risk factor for bacterial pneumonia. *S. aureus*, *Legionella*, *S. pneumoniae*, and *Pseudomonas* have been shown to be more prevalent in patients with HIV.[18] Additionally, *S. pneumoniae* is commonly seen at the extremes of age, in patients with alcohol use disorder, or in those with asplenia, multiple myeloma, or sickle cell disease.

Details of the clinical history also may provide a clue as to the underlying pathogen. Pneumococcal pneumonia may be associated with a single severe rigor with fever and has been associated with symptomatic outbreak of herpes labialis. The abrupt onset of illness with recurrent (over several days) shaking chills, particularly if associated with mild diarrhea for 1 or 2 days, may suggest Legionnaires' disease. Gastrointestinal symptoms and confusion may be seen with any infection, but they are particularly notable in pneumococcal pneumonia and Legionnaires' disease.

The pace and timing of the patient's illness is important to consider. A patient with delayed presentation and underlying risk factors for aspiration or esophageal fistula should prompt consideration of anaerobic organisms, including *Bacteroides* spp., *Fusobacterium* spp., *Peptostreptococcus* spp., *Peptococcus* spp., and *Prevotella* spp. (Chapter 127). Prior mild respiratory illness ("the flu"), followed by improvement and then rapid deterioration, is suggestive of bacterial superinfection of viral pneumonitis and is consistent with *S. aureus* or other bacterial infection, especially in the patient with known prior respiratory colonization or with positive nasal swab screening.

■ Physical Examination

Physical examination may provide very important clues regarding the etiology of pulmonary infection. Skin lesions may suggest underlying pathogens, such as ecthyma gangrenosum, which is associated with Gram-negative infections (in particular, *Pseudomonas*). Erythema multiforme and bullous myringitis are associated with *M. pneumoniae* infection. Evidence of injection drug use, such as cutaneous abscesses, or evidence of needle injury ("track marks") may suggest bacteremic pneumonia. Additionally, Janeway lesions, Osler nodes, and splinter hemorrhages are signs that suggest endocarditis.

Endovascular infection may be complicated by septic pulmonary emboli if the disease is based in the right side of the heart or venous circulation, or if there is a left-to-right intracardiac shunt. Retinal examination may support bacteremia as the underlying pathogenesis if there is evidence of endophthalmitis.

Periodontal disease or absent gag reflexes are risk factors for aspiration pneumonia. Chest splinting may impair clearance of pulmonary secretions and increase risk of infection. Neurologic symptoms can be easily overlooked, but they may provide valuable clues. The elderly patient with pneumonia often presents with a globally depressed mental status, while an immunocompromised host may have focal neurologic deficits consistent with embolic or invasive disease (Chapter 123).

Dullness to percussion, bronchial breath sounds, and egophony ("E to A changes") are suggestive of pulmonary consolidation. Patients infected with *Pneumocystis jirovecii*, *Mycoplasma*, or viruses may have a normal chest examination despite abnormal chest radiographs (or vice versa) and marked hypoxemia.

■ Routine Laboratory Tests

Many systemic processes are reflected in abnormalities of blood counts, urinalysis, or routine blood chemistries. Most patients with bacterial pneumonia have an elevated white blood cell count and increased neutrophils. Viral pneumonia may depress the white blood cell count, particularly the number of lymphocytes. Mixed hematologic pictures are common. Hyponatremia has been associated with Legionnaires' disease; however, any pulmonary infection can cause SIADH leading to hyponatremia.[19] Mild liver function abnormalities may suggest Q fever, tularemia, miliary tuberculosis, or Legionnaires' disease, but are commonly seen with systemic infection. The presence of pigmented casts in the urine and markedly elevated serum levels of creatine phosphokinase may focus attention on possible influenza virus pneumonia, Legionnaires' disease, or pulmonary infiltrates associated with injection drug use.

■ Biomarkers of Infection

Because of the inflammatory milieu of infection, interest has arisen in assays measuring blood levels of cytokines to predict severity of disease and to aid in diagnosing pneumonia.

Procalcitonin has received much attention as a biomarker. Procalcitonin is released into the blood when systemic inflammation is mediated by a bacterial infection. This phenomenon has been shown to be triggered by bacterial toxins, as well as cytokines, including TNF-α, IL-1β, and IL-6.[20] Procalcitonin release into the bloodstream has not been shown to occur in the context of viral infection. Thus, procalcitonin shows promise as a biomarker for early detection of bacterial infections and for distinguishing these infections from other infectious or inflammatory disorders.

Currently, clinical understanding of optimal use of procalcitonin is evolving. Given its hypothetical utility to differentiate between viral and bacterial processes, enthusiasm has grown about using procalcitonin in the decision process of when to initiate antibiotics. Some institutions have begun to use a procalcitonin level <0.25 mg/mL as a threshold for discontinuing antibiotics in clinically stable patients in whom an alternative and more likely diagnosis has been made, or in those with probable viral infection (based on testing). However, it should be noted that the thresholds for discontinuing antibiotics have not been rigorously studied, and clinically useful ways to deploy the test continue to evolve. Furthermore, pneumonia secondary to infection with *Mycoplasma* spp. and *Chlamydia* spp. has not been shown to be associated with increased procalcitonin levels. Lastly, procalcitonin is only useful when laboratory infrastructure allows for a quick turnaround time.[21] Current U.S. Guidelines from the IDSA/ATS make a strong recommendation against withholding antibiotics in patients with clinically suspected and radiographically proven pneumonia, regardless of the procalcitonin level.[9] In short, procalcitonin should supplement, rather than supplant, clinical judgment.

■ Management

In practice, initial therapy in community-acquired pneumonia is empiric and based primarily on available clinical clues. The selection of drug(s) for empiric therapy depends on the clinical setting and the gravity of the pulmonary process. Selection of specific antimicrobial agents is considered in detail elsewhere (Chapter 125).

In addition to the choice regarding empiric antibiotics, another key decision is whether the patient with suspected pneumonia merits hospitalization. In practice, this is often a function of a judgment as to whether appropriate therapy is available in the community, including adequate social support to care for the patient's needs (e.g., medications, food, comfort), and the ability to bring the patient back for further care, if indicated. Multiple semiquantitative methods have been developed to assist in this process.

■ Pneumonia Severity Stratification

Pneumonia severity stratification tools have been developed to aid to estimate the predicted mortality of a patient presenting suspected pneumonia. There have been a number of scores to assist clinicians in making this decision using predicted mortality. One of the earliest is the PORT (Pneumonia Patient Outcomes Research Team) score, also known as the Pneumonia Severity Index (PSI). This index stratifies patients according to 20 variables organized by age, presence of medical comorbidities, vital signs, specific laboratory results, and imaging findings. Using a point system, patients are assigned to one of five prognostic categories, with group I associated with the lowest and group V the highest predicted mortality. Groups I and II are often managed as outpatients. Group III is considered "borderline." Lastly, groups IV and V are admitted to the hospital or ICU. The PSI has been widely validated and endorsed; however, it is limited by its complexity and number of inputs.[22,23]

In response to the complexity of the PORT, new scorings systems have been developed that are simpler and utilize more accessible parameters. These include the CURB score, the CURB-65 score, and the CRB-65 score. The CURB score uses just four variables: **C**onfusion of new onset, **U**rea >7 mmol/L (19 mg/dL), **R**espiratory rate ≥30 breaths per minute, and **B**lood pressure <90 mm Hg systolic or <60 mm Hg diastolic.[24] In calculating the score, one point is assigned per variable present, and the presence of two or more points signifies increased risk of mortality.[25] The CURB-65 was later developed and added age >65 to the scoring system, defining severe pneumonia and increased mortality risk as presence of three or more parameters.[26] CRB-65 omits the blood urea nitrogen as a factor, thereby obviating the need for a blood draw, and is sometimes used in the outpatient setting.[27]

More recently, scoring indices have been developed to identify cases of severe pneumonia and patients who may require transfer to the intensive care unit once admitted to the hospital. These include the severe community-acquired pneumonia (S-CAP) score, the SMART-COP, and the Risk of Early Admission to the Intensive Care Unit (REA-ICU) index.[28–30] Additionally, the IDSA/ATS has developed criteria to define severe pneumonia and to guide the decision to admit to the ICU. The IDSA/ATS guidelines have been independently validated and include major and minor variables to identify the sickest patients who may ultimately require intensive care–level support. Major criteria include septic shock requiring vasopressors and respiratory failure requiring mechanical ventilation; the presence of one major criterion dictates transfer to an ICU (Table 122-6).[31] There are limited data to suggest that any of these indices is superior in predicting the need for ICU level care.[32] In conclusion, although scoring systems can bolster clinical decision-making, they should not supersede clinical judgment.

TABLE 122-6 Definition of Severe CAP

Requires 1 major criterion or ≥3 minor criteria
Major Criteria
Hypotension from sepsis requiring pressor support
Respiratory failure requiring mechanical ventilation
Minor Criteria
Tachypnea (respiratory rate ≥30 breaths/min)
$\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 250$
Multilobar infiltrates
Altered mental tatus
Leukopenia (white blood cell count <4000 cells/μL) not otherwise explained
Thrombocytopenia (platelet count <100,000/μL)
Hypothermia (temperature <36°C)
Hypotension requiring intravenous fluid resuscitation

RADIOGRAPHIC FEATURES OF PNEUMONIA

In general, identification of infiltrates on chest radiograph is considered the gold standard for diagnosing pneumonia in a patient presenting with clinical signs and symptoms of a pulmonary infection (productive cough, pleuritic chest pain, dyspnea, and fever), as described earlier.[33] According to consensus guidelines, a chest radiograph should be obtained in all patients presenting with suspected pneumonia.[31] However, no radiologic pattern provides a specific etiologic diagnosis (Chapter 28). The radiographic pattern, combined with clinical and epidemiologic information, *may* allow narrowing of the diagnostic considerations while microbiologic data are assembled. Additionally, the severity of radiographic findings or pattern of findings may identify patients at risk of decompensation who require closer monitoring or inpatient admission (Table 122-7).

Interpretation of chest radiographs should be undertaken within the clinical context of the patient's presentation. If a patient presents with a syndrome highly suggestive of CAP, a clear radiograph may represent a false-negative result. In this case, it is reasonable to initiate empiric treatment (Chapter 125). Factors associated with a false-negative radiograph include presentation early in the course of the illness, neutropenia, hypovolemia, or *Pneumocystis jirovecii* pneumonia. In these instances, repeating the chest radiograph is reasonable; computed tomography (CT) of the chest may provide increased sensitivity.

Several radiographic patterns may be helpful to note. These include (1) lobar consolidation, (2) bronchopneumonia, (3) interstitial pneumonia, (4) nodular or cavitating lesions, and (5) a miliary or micronodular pattern. The chest imaging of a particular patient may not fit neatly into one or another of these categories, and multiple patterns may suggest different etiologies or progression of a disease process. The patterns are generally best defined by

TABLE 122-7 Radiographic Features and Differential Diagnosis of Pneumonia in the Immunocompetent Host

Consolidation/focal opacity	*Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, *Chlamydophila pneumoniae*, *Legionella* species, *Staphylococcus aureus*, *Mycobacterium tuberculosis* and "atypical" mycobacteria (*M. avium* complex)
Cavitation	*S. aureus*, anaerobic bacteria, *M. tuberculosis*, Gram-negative aerobic bacteria, *Aspergillus* species, geographic/endemic fungi (*Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis)*
Interstitial infiltrates	Viruses, *M. pneumoniae*, *M. tuberculosis*, geographic/endemic fungi, *Chlamydophila psittaci*, drug-induced
Miliary	*Mycobacterium tuberculosis*, geographic/endemic fungi, viruses, *M. pneumoniae*
Lymphadenopathy	*M. tuberculosis*, viral (EBV, CMV, rubella), geographic/endemic fungi, *Chlamydophila psittaci*, cat-scratch disease

CT scanning, which may also detect patterns within a pulmonary process, including lung necrosis; bronchial obstruction (e.g., due to hilar lymphadenopathy or endobronchial tumor); underlying parenchymal disease that accounts for a pleural effusion, empyema, or loculated fluid collection; bronchiectasis; or fungus balls within cavitary lesions.[34] Subtle changes, including interstitial patterns or infections in immunocompromised hosts (e.g., *P. jirovecii*), are often better assessed using CT scanning (Chapter 123). CT scanning can also assist in determining the best invasive diagnostic approach (e.g., needle aspiration, bronchoalveolar lavage, or open lung biopsy).

■ Lobar Pneumonia

The radiographic infiltrate of lobar pneumonia occurs when organisms induce inflammatory edema in alveoli. When the consolidation involves an entire lobe, the result is classic *lobar pneumonia*. An air bronchogram, or outline of an airway made visible by filling of the surrounding alveoli by fluid or inflammatory exudates, is characteristic of lobar pneumonia. Loss of volume is absent or minimal during the acute stage of consolidation, but some atelectasis may develop due to obstruction of bronchi by exudate. It is generally thought that lobar pneumonia indicates a bacterial process, whereas interstitial infiltrates are more likely to be related to viruses and pneumocystis. However, studies have highlighted significant interobserver variation among radiologists' interpretations of chest radiographs in differentiating bacterial and nonbacterial pneumonia based on radiographic features.[35,36]

A large lobar pneumonia with associated pleural effusion is suggestive of a bacterial process. Most cases of lobar pneumonia are due to *S. pneumoniae*; however, this organism can also present with a variety of radiographic patterns. *K. pneumoniae* is another common cause of CAP, which, like pneumococcal pneumonia, shows homogeneous parenchymal consolidation containing air bronchograms (Fig. 122-1). Although *K. pneumoniae* classically affects the right upper lobe and produces a dense, homogeneous lobar consolidation with bulging of the fissure, these features are not pathognomonic and cannot be relied on for diagnosis without supportive bacteriologic data. The propensity for *K. pneumoniae* to produce tissue destruction and abscess formation may result in a shrunken, rather than an expanded, lobe. Pneumococcal pneumonia may also cause bulging of the fissure, albeit less commonly and less prominently than in *K. pneumoniae*. Extensive alveolar consolidation may occur in a variety of other bacterial causes of pneumonia, including those due to mixed anaerobes of aspiration pneumonia and a variety of Gram-negative bacilli implicated in nosocomial infections.

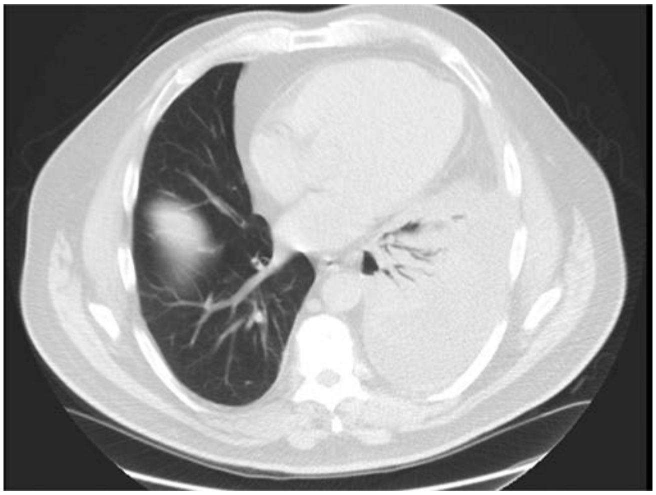

Figure 122-1 CT scan of a patient with CAP, consistent with left-sided lobar pneumonia. Note the evident air bronchograms signifying dense filling of alveoli. *(Reproduced with permission from Dr. M. Kavanaugh.)*

Occasionally, airspace consolidation appears spherical, with rounded edges, and is termed *spherical pneumonia*. Notably, the finding occurs in children. The underlying pathogenesis leading to spherical infiltrates is thought to be mediated by passage of exudate into adjacent alveoli via the pores of Kohn. The most frequent organisms implicated include *S. pneumoniae* or *H. influenzae*. The finding has also been reported with Q fever (*C. burnetii*).

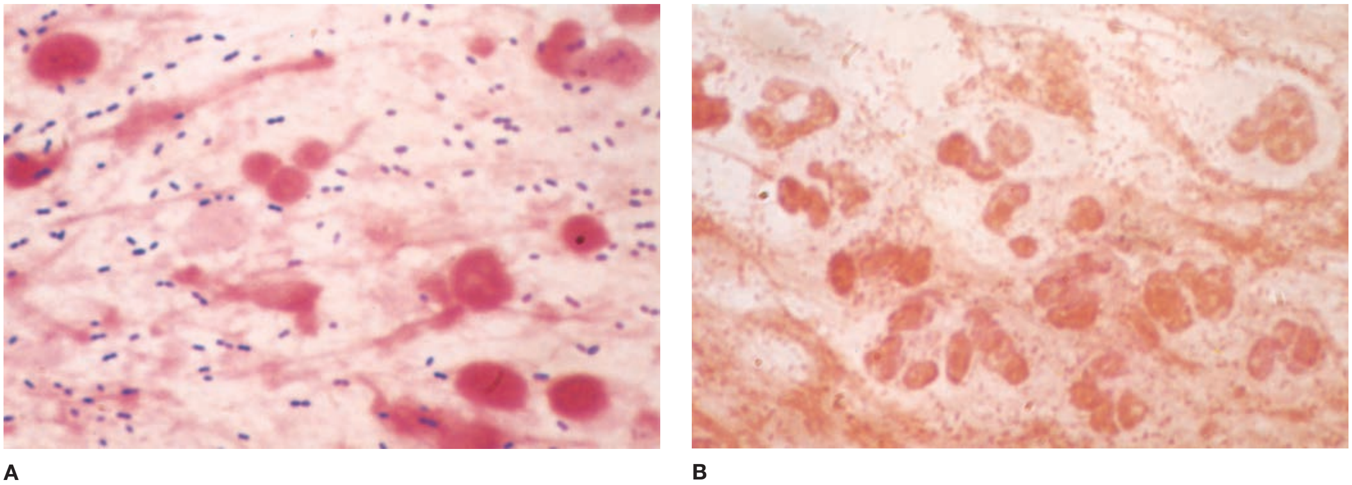
■ Bronchopneumonia

In bronchopneumonia, the focus of infection and the inflammatory response result in epithelial ulceration of the walls of the bronchi and fibrinopurulent exudate filling surrounding peribronchiolar alveoli. This typically occurs in a segmental, patchy, multifocal distribution. Segmental involvement may become confluent, producing a more homogeneous pattern. Bronchopneumonic patterns are commonly observed in pulmonary infections due to *S. aureus* or nonencapsulated *H. influenzae*. Figure 122-2 *shows a Gram stain of common organisms that cause a bronchopneumonic pattern radiographically.*

A bronchopneumonic, rather than lobar, pattern of consolidation is commonly observed when CAP follows viral infection or pneumonia occurs in the setting of underlying bronchiectasis or chronic bronchitis. In the presence of underlying emphysema, the radiographic pattern of pneumococcal pneumonia may also be altered from its usual homogeneous pattern to one characterized by multiple radiolucencies (representing nonconsolidated emphysematous areas) that may be misinterpreted for abscesses.

Segmental bronchopneumonia is the typical radiographic pattern seen with *Chlamydophila pneumoniae* (Taiwan Acute Respiratory Agent [TWAR]), *M. pneumoniae*, and many viral pneumonias. Any of the bacterial species that cause nosocomial pneumonia may produce a radiographic pattern of bronchopneumonic consolidation.

Noninfectious etiologies of bronchopneumonia include aspiration of gastric contents, bronchioloalveolar cell carcinoma, granulomatous disease in pneumoconiosis, sarcoidosis, hypersensitivity



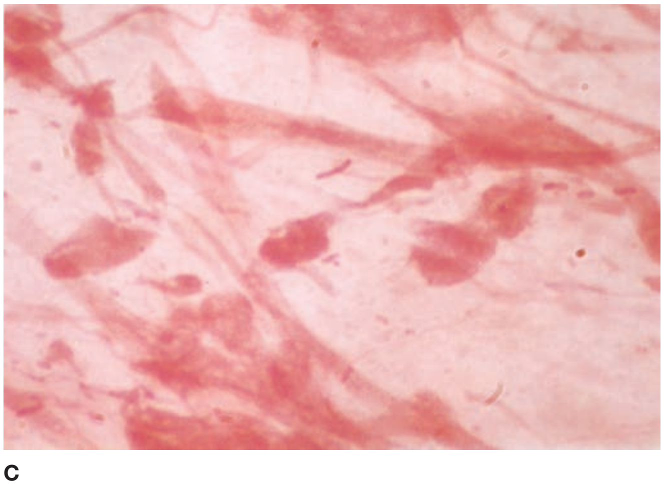


Figure 122-2 **A.** Gram-stained smear of sputum from patient with pneumococcal lobar pneumonia ×1000. In this field there are numerous Gram-positive lancet-shaped diplococci and polymorphonuclear leukocytes. **B.** Gram-stained smear of sputum from patient with bronchopneumonia superimposed on chronic bronchitis. The field (×1000) is teeming with Gram-negative coccobacilli. Many polymorphonuclear leukocytes are present. *H. influenzae* was isolated from sputum as predominant organism. **C.** Gram-stained smear of sputum from patient with lobar pneumonia due to *K. pneumoniae*. In this field (×1000) there are moderate numbers of polymorphonuclear leukocytes and large, thick, Gram-negative bacilli. *(Reproduced with permission from H. Provine.)*

pneumonitis, cryptogenic organizing pneumonia (COP), autoimmune diseases, and bronchiolitis obliterans.

■ Interstitial Pneumonia

A reticular or reticulonodular pattern of infiltration is the radiographic representation of interstitial inflammation—that is, a peribronchovascular infiltrate. In otherwise healthy persons, *M. pneumoniae* is high on the list of community-acquired causes of a radiographic pattern of interstitial pneumonia. In some instances, interstitial infiltration progresses to patchy consolidation of airspaces, most often in the lower lobes. Pneumonia due to respiratory viruses sometimes has an interstitial pattern that progresses to patchy segmental consolidation or to diffuse airspace disease that resembles pulmonary edema. This can appear as ground-glass opacities on CT (Fig. 122-3). *Legionella*,

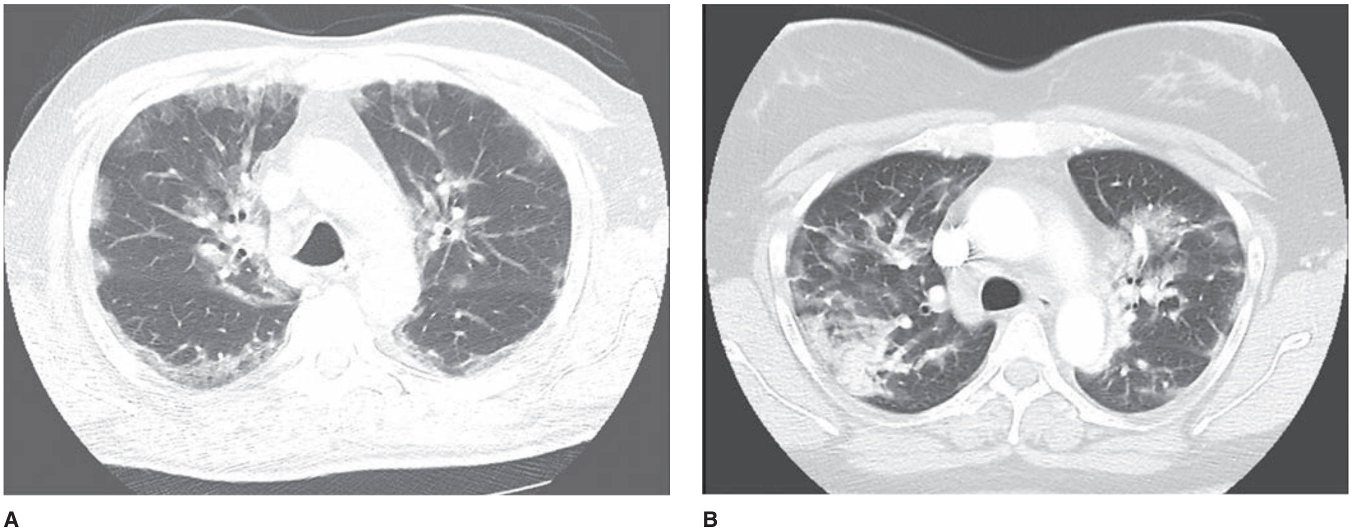

Figure 122-3 Computed tomography of viral pneumonia. **A.** Peripheral ground-glass opacities in a patient with influenza. **B.** Ground-glass opacities and consolidation in a patient with COVID-19. *(Reproduced with permission from Dr. M. Kavanaugh.)*

Pneumocystis, and primary viral pneumonias may manifest as bilateral, diffuse disease. A variety of noninfectious causes of interstitial lung disease (e.g., hypersensitivity lung disease, collagen vascular disease, and sarcoidosis) may also produce a reticular pattern on the chest radiograph (Fig. 122-4).

■ Nodular Infiltrates, Cavitation, and Pneumatoceles

In the current discussion, nodular infiltrates are considered as well-defined, large (>1 cm on the chest radiograph), round, focal lesions. A nodular infiltrate may represent a small abscess secondary to aspiration (without air–fluid levels), a fungal or tuberculous granuloma, or a lesion of pulmonary nocardiosis. Multiple nodular infiltrates may also represent necrotic lesions secondary to septic vasculitis produced by staphylococcal or pseudomonal bacteremia, or the consequences of fungemic spread of *Candida* from an infected intravascular catheter. Infected nodular pulmonary lesions are sometimes caused by septic pulmonary infarcts produced by infected emboli that originate from right-sided bacterial endocarditis, septic thrombophlebitis of pelvic veins, or septic jugular vein phlebitis. Cavitation may be caused by ongoing necrosis of nodules associated with *S. pneumoniae*, *K. pneumoniae*, or *P. aeruginosa* (Fig. 122-5).

S. aureus may cause necrosis of the lung, bronchopleural fistulae, and empyema. Macro- and micro-abscess formation may occur rapidly in cases of *S. aureus* pulmonary infection. Panton-Valentine

Partial clearing in response to combined chemotherapy (cyclophosphamide and prednisone). **B.** Onset with malaise, headaches, and fever in a previously healthy 62-year-old woman. Bilateral maxillary sinusitis. Widespread nodular pulmonary infiltrates are most marked on the right. **C.** Same patient as **B** after 3 years of intermittent combined chemotherapy. Bilateral large masses. **D.** Same patient as **C**, 2 months later. Necrosis within mass in left upper lobe has produced a fluid level.

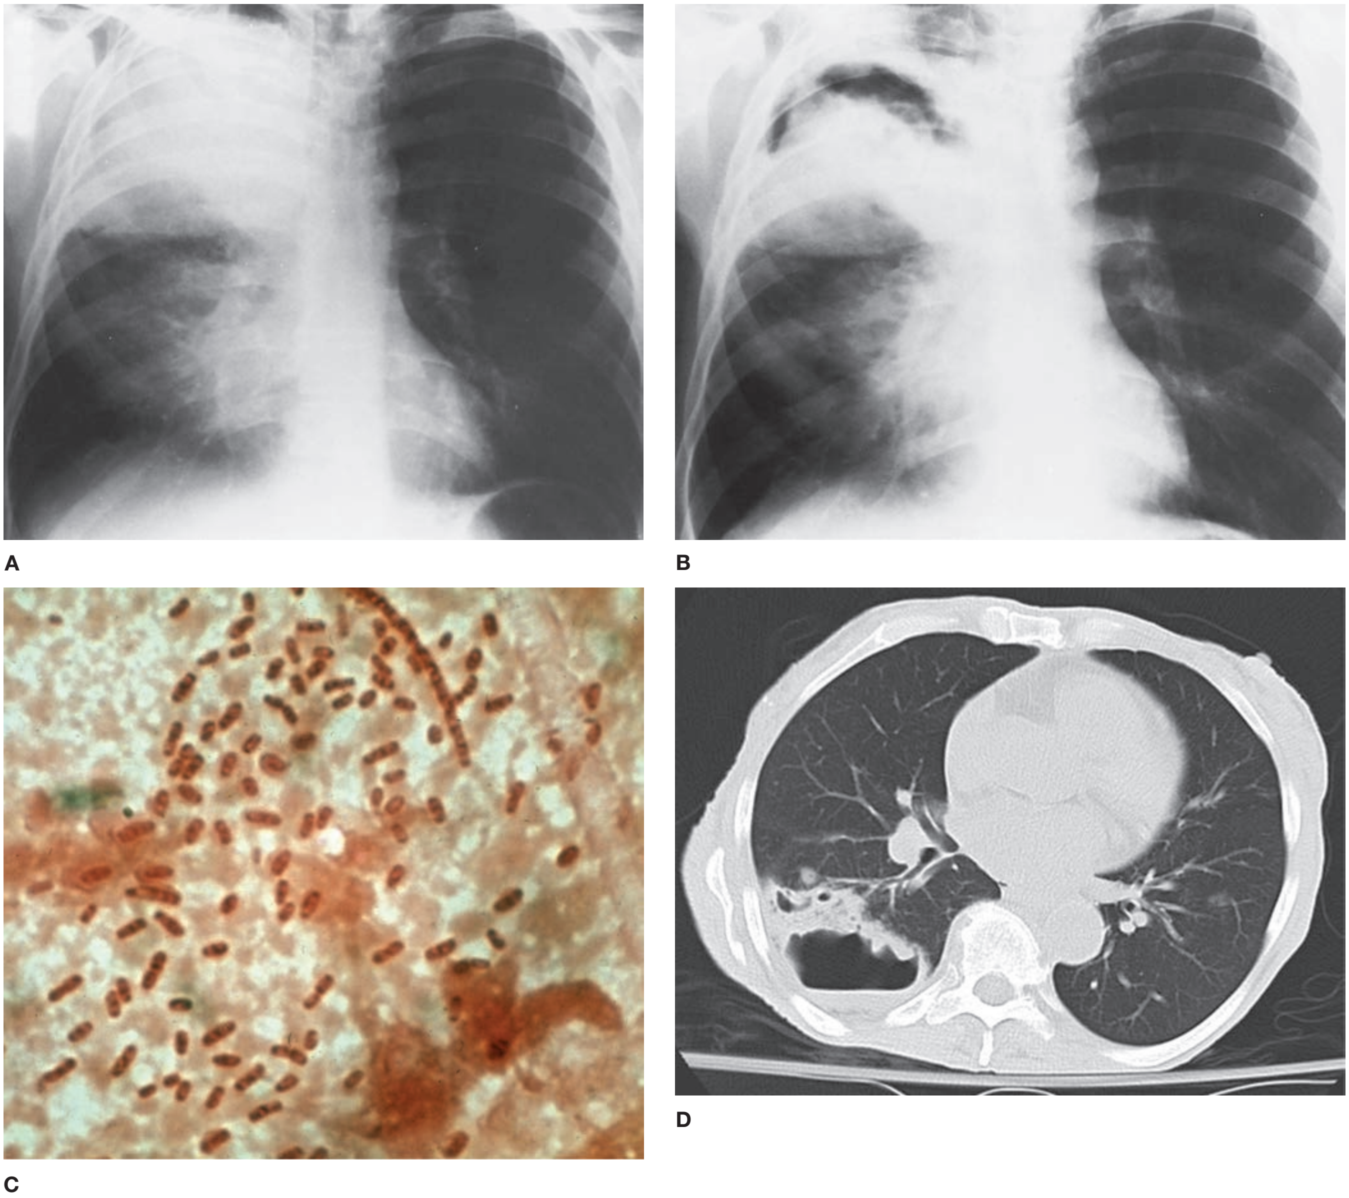

Figure 122-5 **A.** Dense lobar consolidation involving right upper lobe and right middle lobe in an alcoholic patient with *Klebsiella pneumoniae* pneumonia. The minor fissure is bulging downward. **B.** Same patient 7 days later. Despite antibiotic therapy, *K. pneumoniae* pneumonia progressed to become a necrotic process with formation of multiple abscesses. **C.** Sputum Gram stain from patient with *K. pneumoniae* infection reveals Gram-negative rod forms with trace of a surrounding capsule. **D.** A different patient with necrotizing *K. pneumoniae* pneumonia; note the cavitary lesion with air-fluid level. *(**C.** Reproduced with permission from Dr. R. Greene; **D.** Reproduced with permission from Dr. M. Kavanaugh.)*

leucocidin produced by *S. aureus* is associated with necrotizing pneumonia and multilobar involvement. Pneumatoceles occur early in the course of about half of children with *S. aureus* pneumonia. These cystic spaces are believed to be the consequence of a check-valve opening between a peribronchial abscess and an adjacent bronchus. Figure 122-6 illustrates a prominent pneumatocele. Pneumatoceles may also be seen with other causes of pneumonia, including *K. pneumoniae*, *S. pneumoniae*, *H. influenzae*, and *P. jirovecii*.

Aspiration pneumonia may additionally cause cavitation, necrotizing pneumonia, and empyema (Chapter 127). This commonly involves the basilar or superior segment of the lower lobes or the posterior segments of the upper lobes. This predilection depends on the patient's position at the time of aspiration; the lower lobes are involved more frequently when the patient is upright, and the posterior upper lobes are more commonly involved if aspiration occurred while supine.

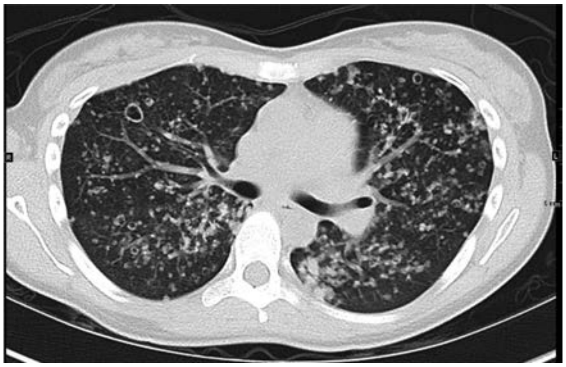

Figure 122-6 Thin-walled, cystic pneumatoceles characteristic of *Pneumocystis jirovecii* pneumonia. *(Reproduced with permission from Dr. M. Kavanaugh.)*

When chronic, cavitary pulmonary disease is most often caused by tuberculosis (Chapter 130). Tuberculosis commonly begins with a focus of pneumonitis, usually in the subapical posterior portion of an upper lobe. This patch of pneumonitis occurs at a latent site of earlier metastatic infection (called a *Simon focus*), produced by lymphohematogenous or hematogenous spread from primary pulmonary tuberculous lesions. Progressive caseation necrosis at the site, followed by drainage of caseous material through the bronchial tree, produces a cavity, as seen in Fig. 122-7. The cavity is encased in a rigid wall of fibrous tissue.

In addition to pyogenic lung abscess and pulmonary tuberculosis, other pulmonary infections may produce chronic cavities. These include infections with *Nocardia*, *Rhodococcus equi*, actinomycosis, and chronic primary pulmonary mycoses (particularly histoplasmosis, occasionally coccidioidomycosis, and, uncommonly, blastomycosis). Sporotrichosis may affect the lung and produce thin-walled cavities. Parasitic infestation of the lung (paragonimiasis, echinococcosis) also may form cavities.

Pulmonary cavities may also occur in noninfectious disorders (e.g., granulomatosis with polyangiitis, lymphoma or bronchogenic carcinoma, bland pulmonary infarcts, and intrapulmonary nodules of rheumatoid lung disease). Pneumatoceles may also be caused by noninfectious processes, including hydrocarbon ingestion, trauma, and positive-pressure ventilation. Cavitary and cystic lesions occur in chronic pulmonary sarcoidosis and in the markedly dilated bronchi of saccular bronchiectasis. Cavities may become superinfected with *fungus balls*. These represent tangled masses of fungal hyphae and debris lying freely within pulmonary cavities. Typically, they represent noninvasive saprophytic growth in the immunologically normal host. The most common organism is *Aspergillus* (usually *A. fumigatus*), and the fungus ball is called an aspergilloma. Invasion of the cavity wall may occur with immune compromise; hemoptysis originating from the cavity wall is common and may be severe. This hemorrhage leads to the classic "halo sign" on CT (Fig. 122-8).

■ Miliary and Micronodular Pulmonary Disease

Disseminated miliary lesions of an infectious nature suggest tuberculosis, nontuberculous mycobacteria, or endemic fungi (e.g., histoplasmosis or blastomycosis) in either the normal or immunosuppressed host. Hematogenous dissemination of tuberculosis may follow initial infection in children or adults. It may also result from breakdown of formerly quiescent sites of pulmonary or extrapulmonary infection. Clinically unexplained fever may be accompanied by small lesions seen on the chest radiograph (so-called "millet seed" pattern); histologically, these lesions are foci of granulomatous reaction and appear as areas of fine nodularity (Fig. 122-9). Similar radiographic lesions occur in the course of hematogenously disseminated bacterial and

mycotic infections, including cryptococcosis and histoplasmosis. In the immunosuppressed patient, a miliary pattern may be seen in disseminated cryptococcal infection or with hematogenous spread of bacterial or *Candida* infection (Chapter 123).

APPLICATION OF RADIOGRAPHIC TECHNIQUES TO THE CLINICAL DIAGNOSIS OF PNEUMONIA

A consistent approach to the incorporation of radiographic imaging in evaluating a patient with suspected pneumonia is helpful. One such approach includes the following four steps.

Comparison of the radiograph with prior studies. Is the process old or new? Are there multiple processes? Has the patient had surgery in the intervening period? Is the spleen enlarged or absent?

Note the presence or absence of an infiltrate. Chest radiograph findings can be helpful in distinguishing which patients will benefit from antibiotic therapy. Absence of radiographic findings of a lower respiratory tract infection can be used to withhold antibiotics in a patient who is not severely ill, and in whom the presenting features are not highly consistent with pulmonary infection. Determining whether the pattern is more consistent with an interstitial or lobar process may be helpful.

Consider confounding variables. If there is no infiltrate, assessment of the probability of a false negative radiographic is useful. Is this patient early in the disease course? Are they dehydrated? Does the patient have risk factors for *Pneumocystis* pneumonia (advanced HIV or prolonged steroid use)? Are the radiographic findings more consistent with a noninfectious etiology (e.g., diffuse pulmonary edema in a patient with decompensated heart failure)?

Consider obtaining a CT scan. CT scanning is highly sensitive to discerning changes unrecognized in plain radiographs and may be useful in guiding invasive procedures.

EXAMINATION OF CLINICAL SPECIMENS AND ESTABLISHMENT OF A MICROBIOLOGIC DIAGNOSIS

The traditional clinical approach to pneumonia places great emphasis on establishing a specific microbiologic diagnosis. An appropriately stained smear of sputum or pleural fluid, bronchoalveolar lavage (BAL) fluids, blood buffy coat, skin lesions, or throat swabs *may* provide a provisional diagnosis and allow deployment of more targeted antimicrobial therapy.[37]

In practice, most patients with pneumonia are treated empirically. Examination of sputum samples should not delay treatment. For community-acquired pneumonia in the outpatient setting, pretreatment blood cultures and sputum cultures are not recommended routinely. Indications for obtaining microbiologic data include patients with severe disease, hospitalized patients, patients at risk of multidrug-resistant organisms (such as patients with cystic fibrosis or immunosuppressed patients), and patients empirically treated for *Pseudomonas aeruginosa* and MRSA.[9]

Noninvasive studies may provide information indicating the specific microbial cause of a pulmonary infection or may narrow the field of likely etiologic agents. Culture of sputum, blood, or pleural fluid may provide a specific diagnosis when evaluation of sputum smears have not, either because the infecting agent cannot be distinguished from components of the normal upper respiratory tract flora incorporated in the specimen, or because the particular microorganism is not visible on Gram-stained smear (e.g., *Mycobacterium*, *Mycoplasma*, *Legionella* species). The availability of rapid culture–independent microbiologic assays for viral respiratory infections and for some common pathogens (e.g., antigen detection for pneumococcal or *Legionella* infections, rapid viral screens) has, to some extent, reduced the need for other modalities of diagnosis.[38]

Tests of Respiratory Specimens

A variety of laboratory tests may be performed on respiratory specimens and are considered below.

Specimen Quality

Adequate quality of samples of expectorated or induced sputum for staining and culture is very important. Poor-quality specimens typically have high numbers of squamous epithelial cells due to contamination with oropharyngeal secretions. A microorganism isolated from deeply coughed sputum cultures obtained before the initiation of antimicrobial therapy is considered clinically relevant if detected in respiratory specimens, blood, or both, and the specimen is of good quality, that is, contains >25 leukocytes and <10 squamous epithelial cells per low-power field. The presence of 10 or more squamous epithelial cells (normally exfoliated from the oropharynx) per low-power (×100) magnification field indicates that the specimen is unsatisfactory; culture of such a specimen correlates poorly with results from culture of a transtracheal aspirate (Fig. 122-10).

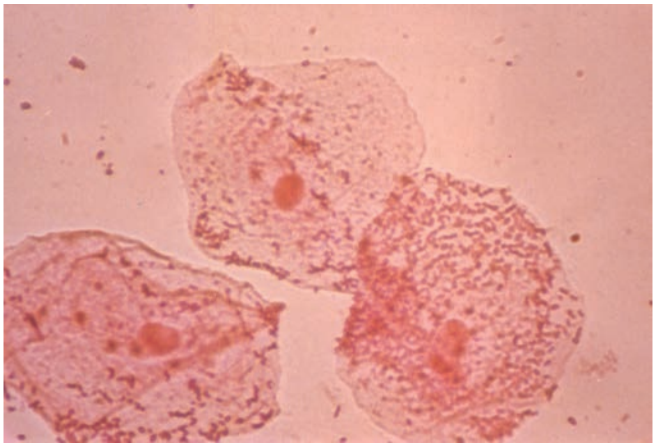

Figure 122-10 Three large oropharyngeal epithelial cells from a specimen of "sputum" that is inadequate for Gram stain analysis and culture because of its origin in the upper respiratory tract. Note the large number of organisms agglutinated on the surface of the squamous epithelial cells (×400).

The presence of numerous polymorphonuclear neutrophils on a Gram-stained smear (10–25 neutrophils or more per low-power microscopic field) in the absence of an excessive number of squamous cells (see above) is indicative of a good specimen for bacteriologic evaluation. One study demonstrated that, in contrast to sputum of low quality, where culture positivity was 14.5%, sputum of good quality was associated with culture positivity of 63.2%.[39]

Some laboratories reject inadequate sputum specimens and notify clinicians to request a repeat specimen, whereas other laboratories never reject a sputum, but abbreviate the quality of the specimen on the result report. Specimens should be plated for cultures within 2 h of receipt or stored at 4°C until plated. In practice, many patients with pneumonia (~30%) cannot produce good sputum samples, and many have had prior therapies that alter the success of microbial cultures (15%–30%); 40% to 60% of cultures are negative.[40,41] A specific etiology can be established in fewer than 50% of cases using routine studies (sputum and serologies). Sputum induction using inhaled nonbacteriostatic saline mist and chest percussion may increase the yield for *Pneumocystis*, mycobacteria, and malignancy on cytologic examination. Cytologic assessment is not necessary for screening specimens for detection of *Legionella*, mycobacteria, or any specimens obtained using induced sputum.

Examination of Gram-stained Smears for Bacteria

Initial examination of Gram-stained sputum smears can be of major value in pinpointing a bacterial cause of pneumonia and guiding initial and subsequent therapy, especially when a single morphologic type of bacteria predominates. In clinical practice, therapy is generally initiated prior to the availability of sputum examination.

Many bacterial respiratory tract pathogens have characteristic morphologies and strongly suggest an etiologic role when present in a suitable respiratory specimen containing inflammatory cells (in the absence of neutropenia). Such organisms include *S. pneumoniae* (Gram-positive oval or lancet-shaped diplococci), *H. influenzae* (small, pleomorphic Gram-negative bacilli), *M. catarrhalis* (Gram-negative, biscuit-shaped diplococci), or the similar-appearing *Neisseria meningitis*, enteric Gram-negative bacilli (indistinguishable from one another with respect to species, except for large encapsulated rods that are suggestive of *Klebsiella*), and *S. aureus* (large Gram-positive cocci in small groups or clusters) (Fig. 122-11). Since normal oral flora includes a variety of streptococcal species that are morphologically somewhat similar to *S. pneumoniae*, sputum smears may be misinterpreted. Thus, a predominance of Gram-positive diplococci in multiple oil immersion fields needs to be observed to implicate *S. pneumoniae*.[42] A quantitative aspect to the evaluation has been suggested: at least 10 Gram-positive, lancet-shaped diplococci per oil immersion field predicts the isolation of *S. pneumoniae* from sputum cultures with a specificity of 85% and sensitivity of 62%. A systematic review and meta-analysis of 24 studies, including 4533 patients with sputum Gram stains for diagnosing bacterial pathogens in community-acquired pneumonia, has been published. It demonstrated a specificity of 91% and sensitivity of 69% for detecting *S. pneumoniae*, and a specificity of 97% and sensitivity of 76% for detecting *H. influenzae* in good-quality sputum specimens. Bacterial pathogens were identified in 73% of good-quality specimens and in 36% of all specimens, regardless of quality.[43]

In appropriate clinical and radiographic settings, Gram-stained smears may be helpful not only in the etiologic diagnosis of community-acquired bacterial pneumonia due to the usual respiratory pathogens, but also in supporting a diagnosis of atypical pneumonia when sputum examinations repeatedly show neither neutrophils nor bacteria (*Mycoplasma* or *Legionella*). Uncommon bacterial species may be implicated in a pulmonary infection on the basis of unusual morphology. Figure 122-12 shows a Gram-stained smear

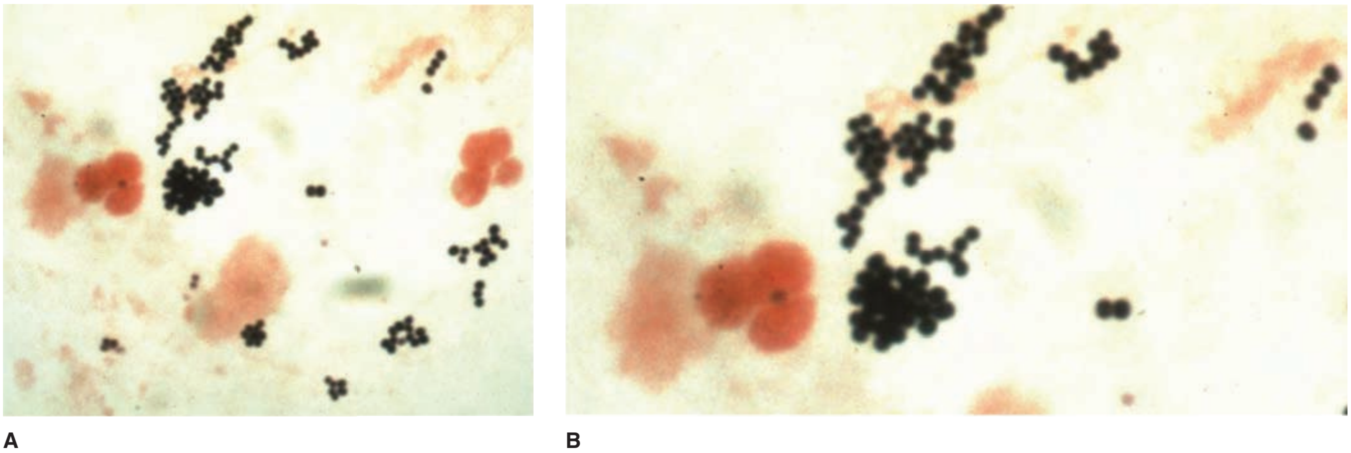

Figure 122-11 *S. aureus* on Gram-stained smear from patient with history of injection drug use with right-sided bacterial endocarditis. There are polymorphonuclear leukocytes and clusters of Gram-positive cocci. *(Reproduced with permission from H. Provine.)*

of irregularly staining, beaded, delicate, Gram-positive, branching filaments that suggest either *Nocardia* or *Actinomyces* (Chapter 137). Several organisms that are uncommon causes of pulmonary infection have morphologic characteristics that may mimic other, more common respiratory pathogens. *Pasteurella multocida* and *Acinetobacter* species, both small Gram-negative coccobacilli, have each been mistaken for either *H. influenzae* or *M. catarrhalis* in sputum of patients with pulmonary infections.

Sputum or pleural fluid with foul odor suggests the presence of anaerobic organisms and underlying lung abscess, aspiration pneumonia, empyema, or occasionally, bronchiectasis. In these settings, findings on Gram-stained smear may corroborate the

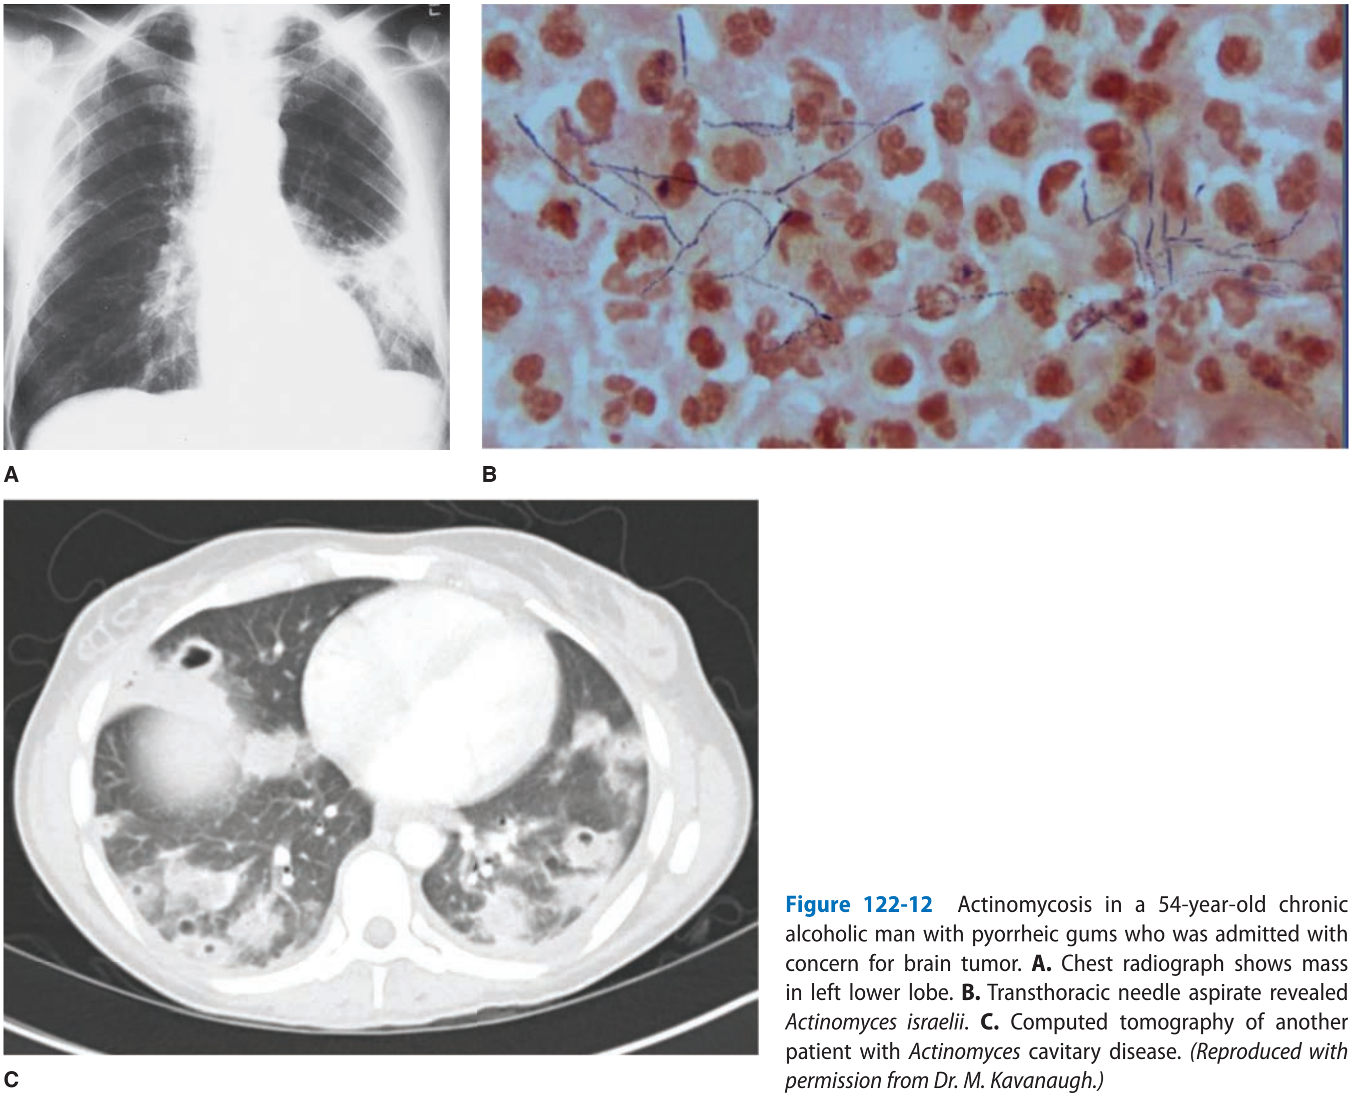

Figure 122-12 Actinomycosis in a 54-year-old chronic alcoholic man with pyorrheic gums who was admitted with concern for brain tumor. **A.** Chest radiograph shows mass in left lower lobe. **B.** Transthoracic needle aspirate revealed *Actinomyces israelii*. **C.** Computed tomography of another patient with *Actinomyces* cavitary disease. *(Reproduced with permission from Dr. M. Kavanaugh.)*

preliminary diagnosis. Organisms of the *Bacteroides melaninogenicus–Bacteroides asaccharolyticus* group are small, Gram-negative coccobacilli. *Fusobacterium nucleatum* is a long, tapering, pale-staining, Gram-negative bacillus with irregular, Gram-positive internal granules. Purulent secretions or pus from such anaerobic infections contains numerous neutrophils and, usually, a mixture of bacterial species, including anaerobic and microaerophilic streptococci seen on stained smear.

Examination of Acid-fast Stained Smears for Mycobacteria

Acid-fast stains include fluorescent stains, such as auramine-rhodamine, and carbol-fuchsin-based stains, such as Kinyoun and Ziehl-Neelsen, which are viewed by light microscopy. Kinyoun cold staining is a modification of the classical Ziehl-Neelsen method that excludes the heating step during staining and, therefore, uses a higher concentration of carbol fuchsin.[44] Most laboratories currently employ a fluorochrome stain with auramine–rhodamine (Mycobacteria fluoresce orange-yellow) for initial examination of sputum or other body fluids, as it is easier to visualize fluorescent rods on a dark background than pink rods on a blue background.[44] Although less sensitive than culture (50%–65% vs. 80%–85%) for the diagnosis of tuberculosis, acid-fast smears are performed on direct specimens because the positive predictive value is very high, particularly in respiratory specimens. A positive smear indicates that a species of mycobacteria is present, although not necessarily *M. tuberculosis*. Molecular diagnostics (e.g., polymerase chain reaction [PCR]) for *M. tuberculosis,* available for direct application to clinical specimens, provide great promise in reducing the global burden of tuberculosis by offering a rapid and accurate diagnosis.

Atypical mycobacteria may be demonstrated on sputum smears of patients whose pulmonary disease is usually characterized by slow progression, or who have underlying immunocompromise (Chapter 131). Disseminated *M. avium complex* infection in patients with advanced HIV is usually diagnosed by isolation of the organism from AFB isolator blood cultures or by histopathologic diagnosis on biopsy. The organism may be demonstrated on acid-fast smears and culture of respiratory secretions, however, even with little radiographic evidence of pulmonary infection directly attributable to its presence. Improved culture techniques are available to more rapidly isolate mycobacteria from clinical specimens. Modified Ziehl–Neelsen–stained smears are helpful in detecting *Nocardia*, which appear as a partially acid-fast, filamentous, branching rod with beaded appearance. Their appearance sets them apart from *Actinomyces* and *Streptomyces*, which may appear similar on Gram stain, but are not acid-fast.

Fungal Wet Mount Preparations

Fungal wet mount preparations using potassium hydroxide (KOH) or smears stained with the Calcofluor white chemifluorescent agent are employed when epidemiologic considerations suggest community-acquired pulmonary mycoses (particularly coccidioidomycosis and blastomycosis). Fungi are fairly refractory to the activity of KOH, while human tissues are dissolved, clearing the specimen and making the microscopic demonstration by Calcofluor staining of the fungi much easier. Calcofluor white binds to chitin; hence, it is particularly useful for highlighting the cell wall of fungi in clinical specimens.[45] The sensitivity of Calcofluor-KOH examination of sputum ranges from 50% to 90% in patients with pulmonary blastomycosis. The examination should be a routine part of evaluation of respiratory secretions and lung biopsy specimens from immunocompromised patients in whom additional fungal pathogens (e.g., *Aspergillus* and mucormycosis) may be present. In patients with allergic bronchopulmonary aspergillosis (ABPA), or in whom *Aspergillus* is unexpectedly detected in sputum, the presence of fungal hyphae must be interpreted in the appropriate clinical context.

Rapid Detection by Direct Immunofluorescent Microscopy

Direct fluorescent antibody (DFA) staining may be useful in rapid diagnosis of respiratory tract pathogens. Rapid viral diagnosis by DFA (turnaround time, ∼2 h) may be applied to a variety of specimens, including bronchial lavage or brushings and nasopharyngeal swabs or washings. The technique uses a pool of monoclonal antibodies to influenza and other common respiratory viruses to directly detect infected cells obtained from clinical specimens. DFA sensitivity and specificity are dependent on the skill of the personnel performing the test.[46]

Besides the molecular diagnostics used to evaluate for P. jirovecii nucleic acids, immunofluorescence with monoclonal antibodies against *P. jirovecii* is the most widely used diagnostic technique for diagnosis, demonstrating a sensitivity of 69% to 92%.

Some caveats of DFA staining should be noted. Use of DFA staining for *L. pneumophila* is not recommended in examination of sputum specimens because of the presence of cross-reacting species (e.g., *Bacteroides* species, *Pseudomonas* species, *Bordetella pertussis*) in the upper respiratory tract. However, biopsy specimens of lung (obtained via needle, bronchoscopic, or surgical techniques), bronchoscopic aspirates, BAL washings, and pleural fluid samples are suitable for DFA staining for *L. pneumophila*. Although DFA was one of the first diagnostic tests developed for *Legionella*, due to its technical complexity and modest sensitivity, DFA testing of respiratory samples is rarely used.[47] In addition, although anti–*B. pertussis* DFA may be used on nasopharyngeal aspirate smears in a presumptive case of pertussis, because of its poor sensitivity (only 50%–65%), DFA is no longer in the CDC's diagnostic algorithm for pertussis.

Special Stains for the Diagnosis of *Pneumocystis* Infection

Historically, a variety of stains (toluidine blue O, methenamine silver, Wright–Giemsa, Diff-Quik, Calcofluor) have been useful in identifying *P. jirovecii* cysts in induced sputa or BAL specimens, or on imprint smears of lung tissue specimens. Due to limited sensitivity and specificity of these stains, we prefer use of DFA, as described previously; however, in resource-limited settings, these stains are still used.[48] Toluidine blue O and methenamine silver stain only the cyst (typically <10% of the organism burden), not the trophozoite forms of *P. jirovecii*. Giemsa and Diff-Quik stain trophozoites and intracystic sporozoites.

Sputum Cultures

In most patients with common types of community-acquired and nosocomial bacterial pneumonias, the etiologic diagnosis can be made based on the combined results of a sputum Gram stain and culture of a freshly obtained sputum specimen (see earlier discussion).

Like the Gram stain, sputum cultures can be difficult to interpret. Culture preparation generally entails streak dilution on chocolate agar, blood agar, and MacConkey agar. Expectorated sputum should not be cultured anaerobically, since contamination with oral anaerobes is inevitable. Many pathogens are fastidious, and normal flora may overgrow them. A time delay of >2 h from collection to incubation is associated with substantial loss of pathogen detection. Blood agar best supports the growth of Gram-positive cocci and most Gram-negative rods and is especially useful for evaluation of the colony morphology and hemolysis of streptococci. MacConkey agar is selective for Gram-negative bacteria and is used to determine bacterial ability to ferment lactose (lactose-positive or -negative organisms). Chocolate agar allows recovery of *H. influenzae* and other fastidious organisms. Because patients with Legionnaires' disease often have little sputum production, and since growth requires special media, most attempts to isolate *Legionella* entail procurement of specimens obtained by sputum induction, fiberoptic bronchoscopy, lung biopsy, or thoracentesis. Cultures of materials obtained are plated on buffered charcoal-yeast extract (BCYE) agar. Occasionally, *Legionella* species can be isolated from sputum with the use of a semiselective medium—either BCYE or BCYE-containing cefamandole, polymyxin B, and anisomycin. Culture sensitivity ranges from 15% to 95%; higher sensitivities are seen in severely ill patients.[47] Culture is the most definitive method for diagnosis of *Legionella* infection. Unfortunately, colonies may take 5 or more days to appear.

Cultures for mycobacteria are undertaken when clinical circumstances raise the possibility of pulmonary infections due to *M. tuberculosis* or atypical mycobacteria. The use of solid culture medium, such as Lowenstein-Jensen (LJ) medium, is more cost-effective in resource-poor settings.[49] Similarly, cultures of sputum for primary invasive mycotic agents (e.g., *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) are dictated by clinical and epidemiologic circumstances. The yield of cultures of bronchial washings in patients with pulmonary blastomycosis approaches 100%, but the confirmation of a diagnosis may take up to 5 weeks.[50] In immunosuppressed patients, cultures of sputum are also directed toward a variety of opportunistic fungi, including *Cryptococcus neoformans*, *Aspergillus* species, and Mucoraceae. Given its superior yield, a fungal-specific medium, for example, Sabouraud dextrose agar, should be included at the time of initial specimen setup in clinical scenarios in which *Aspergillus* spp. (or other molds) are considered possible pathogens.[51]

Most hospitals do not have facilities for isolating viruses by tissue culture. This poses little problem in dealing with most community-acquired viral pneumonias, for which viral isolation is not necessary and the cost prohibitive. Viral isolation from throat washings is warranted in exceptional circumstances, for example, to understand the pathogenesis and infectivity of a specific novel viral agent, such as SARS-CoV-2.

Cultures may be grown in cell lines susceptible to the viral infections under consideration in either standard "tube cultures" or "shell vial" cultures. (Rapid culture within 24–48 h is achieved by centrifugation of specimens against the cultured cells.) Viral replication in tissue culture can be confirmed within 48 h after inoculation using fluorescent monoclonal antibodies. Because CMV and herpes simplex are frequently present in the oral and respiratory secretions of immunosuppressed patients, isolation of these viruses tends to include many false positives. In practice, diagnostic cultures (e.g., for CMV, other herpesviruses, and adenovirus) have been replaced by quantitative molecular amplification assays (e.g., nucleic acid amplification tests [NAATs] and PCR) or antigen detection systems that are more rapid and cost-efficient than culture systems (Table 122-8).

Molecular Diagnostic Testing

A variety of NAATs are available for the direct detection of pulmonary pathogens. These tests are more sensitive and specific than traditional antigen tests or viral cultures. Using an array of diagnostics, likely pathogens may be detected in 67% to 89% of cases of CAP. *S. pneumoniae* remains the most common pathogen at 38% and is more often detected by molecular and urinary tests than sputum

TABLE 122-8 Assays for Viral Agents of Adults

Virus (Type)	Season	Culture/Specimen	Culture Days to Positive	DFA/Serology/ Antigen	Molecular Amplification+

culture and examination.[52] Most clinical laboratories have employed NAAT for rapid identification of influenza viruses, as this is the diagnostic gold standard in clinical virology. A recent meta-analysis investigating rapid viral NAAT for influenza showed a pooled sensitivity of 90.9% and specificity of 96.1%.[53] Testing has been shown to reduce unnecessary antibiotics, improve appropriate use of antivirals, decrease hospital stay, and improve infection control efforts. As seen during the global SARS-CoV-2 pandemic, these assays can be used to identify emerging pulmonary pathogens as well.

In some major medical centers, PCR assays for the detection of *C. pneumoniae* and *M. pneumoniae* on nasopharyngeal or throat swab specimens are available. They markedly shorten the time required to isolate organisms by culture (by up to 3 weeks). These new testing capabilities have been entered into new guidelines—for example, the IDSA recommends MRSA nasal screening in patients with HAP or VAP with the intent that a negative test will allow for narrowing of the antibiotic regimen.[9] NAAT assays may be incredibly useful to clinicians; however, they must be used in the context of sound clinical judgment and only when results will impact treatment decisions. For example, IDSA recommends testing for influenza using NAAT assays during periods of high prevalence of the virus within the community.[9]

PCR tests can detect *M. tuberculosis* (as distinct from nontuberculous mycobacteria) directly in sputum and BAL specimens. The World Health Organization endorsed the use of Xpert MTB/RIF (Cepheid, Sunnyvale, California, United States) in 2010 and has since published policies for its global implementation, based on its ease of use in the field, its provision of a result while a patient is waiting, and its diagnostic accuracy. The Xpert MTB/RIF test provides results in about 2 h. Its sensitivity in smear-positive respiratory specimens is 98% to 99% and in smear-negative specimens is 68% to 90%, depending on the number of specimens tested. In countries with a higher prevalence of multidrug-resistant tuberculosis, rifampin resistance is a useful predictor of this finding. The Xpert test also screens for the most common rifampin resistance mutations by interrogating the rifampin resistance–determining region of *rpoB* in *M. tuberculosis*.[54,55]

Molecular detection of herpes simplex virus, adenovirus, cytomegalovirus, Epstein-Barr virus, and other pathogens is used primarily with blood specimens, but it may also be used in samples of BAL or CSF.

In immunosuppressed patients with pneumonia, a broad array of opportunistic viral infections (e.g., CMV, RSV, varicella-zoster virus, herpes simplex) are diagnostic considerations. Strict criteria for CMV pneumonia include demonstration of the virus, typical cytologic and pathologic changes, and absence of other evident pathogens.[56] These criteria are applicable in non-immunocompromised patients, in whom CMV is frequently isolated (likely due to shedding), but in whom CMV rarely causes pneumonia. Isolation of CMV from BAL fluid or blood in bone marrow transplant recipients with pneumonia may be sufficient to establish a presumed diagnosis and to institute treatment, particularly in view of the high frequency and mortality of CMV pneumonia in these patients. Commercially available molecular amplification tests for other pulmonary pathogens include *P. jirovecii*, *L. pneumophila*, and *Aspergillus* spp. In patients with severe immunocompromise who are suspected of having invasive pulmonary aspergillosis, the American Thoracic Society (ATS) recommends the inclusion of *Aspergillus* PCR in BAL and serum testing as part of the evaluation (as well as other diagnostics).[51] One drawback with all PCR testing is that it is overly sensitive—that is, the test may detect organisms even in absence of clinical illness and, hence, does not differentiate between colonization and infection.

Recently, highly sensitive and specific multiplex molecular assays for numerous possible respiratory pathogens using the same specimen have been adopted by some clinical laboratories.[57] Until recently, these included respiratory viruses and some "atypical" pathogens, for example, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella* spp. The Flu SC2 Multiplex Assay (Centers for Disease Control and Prevention, Atlanta, Georgia, United States), used to diagnose infection with influenza A, influenza B, or SARS-CoV-2, is now commercially available.[58] Appropriate specimens for testing include nasopharyngeal swabs, nasal washes, sputa, and bronchoalveolar lavage.

An additional, culture-independent technique includes metagenomic next-generation sequencing (mNGS). Briefly, mNGS is a molecular diagnostic that sequences all nucleic acid in a clinical specimen. The sequences are then referenced against a database of organism genome sequences. The technique has been described as the "needle in a haystack" approach and is generally less sensitive and specific than targeted molecular diagnostics. Usefully, genotypic resistance profiles are generated through mNGS and may impact antimicrobial choices. Given that a causative pathogen is not often identified, the technique may be useful under selected circumstances.

■ Nonmicrobiologic Clues to Pulmonary Infection

Occasionally, in the setting of apparent pulmonary inflammation and features atypical for infection, microscopic examination using stains other than Gram stain may be indicated. For example, Wright-stained smears may show the presence of eosinophils in allergic pulmonary aspergillosis or in other causes of pulmonary infiltrates accompanied by eosinophilia. Birefringent calcium oxalate crystals (needle-like in rosettes or arranged like sheaves of wheat) in sputum cytologic specimens have been reported as suggestive of pulmonary infection with *Aspergillus* (including aspergilloma and, occasionally, invasive aspergillosis).

In the intubated or tracheotomized patient, whose tracheobronchial secretions commonly contain neutrophils and often some bacteria on Gram-stained smears, it may be difficult to distinguish between colonization and nosocomial pneumonia.[59] The presence on light microscopy (×400) of characteristic elastin fibers with split ends (seen in a tracheal aspirate to which a drop of 40% KOH has been added), in the appropriate clinical setting, is a strong indicator of a necrotizing pulmonary infection.

■ Tests from Nonrespiratory Specimens

A variety of nonrespiratory specimens may be useful in the evaluation of patients with suspected underlying pneumonia.

Blood Cultures

Blood cultures should be performed prior to initiation of antibiotics in hospitalized patients with suspected bacterial pneumonia.[60] Bacteremia occurs in approximately 30% of patients with pneumococcal pneumonia, who represent up to two-thirds of those with positive blood cultures.[61] Blood cultures are more often positive in sicker patients, including those with hypotension, renal and liver dysfunction, pleurisy and tachypnea, and thromboembolic disease. Bacteremia in patients with pneumonia may indicate that the pulmonary infection is secondary to a focus of infection elsewhere (e.g., acute right-sided *S. aureus* endocarditis or *Pseudomonas aeruginosa* infection of thermal burns). *Legionella pneumophila* has been isolated with some frequency from automated radiometric blood culture bottles, but blind subculture onto BCYE agar is necessary because growth in the liquid medium does not achieve detectable levels. In patients with AIDS and disseminated *M. avium-intracellulare* infection, mycobacterial blood cultures are almost always positive. The lysis centrifugation technique permits rapid isolation of the mycobacterium and quantifies the intensity of bacteremia.

Antigen Testing

The quellung reaction was extensively used in the pre–antimicrobial agent era to identify *S. pneumoniae* in sputum.[13,62] It entails the use of light microscopy to detect capsular swelling (*Quellung* is the German word for swelling) after pneumococcal antiserum has been added to a loopful of sputum. The occurrence of the quellung reaction was shown to correlate closely with the presence of *S. pneumoniae* in sputum culture in about 90% of the patients. Pneumococcal antigens may also be detected in the sputum of patients with pneumococcal pneumonia using ELISA, latex particle agglutination, or counterimmunoelectrophoresis; none of these techniques is commonly used at present. Antigen detection in sputum may have a sensitivity as high as 70% to 90%; however, specificity is a problem, with about 20% false positives, probably due in part to the difficulty in distinguishing oropharyngeal contamination from colonization.

In many patients, a sputum-based diagnosis is not easy; either an etiologic diagnosis cannot be made based on initial smears or cultures, or antimicrobial therapy may have been initiated before cultures were obtained or adequate sputum samples available. For adults with severe CAP, urinary antigen tests for *S. pneumoniae or Legionella* may be helpful.[9] In adults hospitalized with CAP due to *S. pneumoniae*, generally without bacteremia (the presence of which increases sensitivity), the sensitivity of the pneumococcal urinary antigen assay is 71% and specificity 96%.[63,64] The *L. pneumophila* antigenuria test is easy to perform, is rapid, and is positive despite prior antimicrobial agent administration. Antigenuria may persist for weeks or months after recovery from pneumonia.[65] The assay is available only for *L. pneumophila* serogroup 1, which is responsible for about 80% of *L. pneumophila* infections.

When respiratory viruses are circulating in the community, nasal swabs for viral antigens (influenza, parainfluenza, metapneumovirus, adenovirus, RSV) are often helpful, particularly in the immunosuppressed patient. Rapid, more accessible, point-of-care antigen tests for influenza and SARS-CoV-2 have good specificity but only 50% to 70% sensitivity; retesting using more sensitive assays may be required if clinical suspicion is high.[66,67] For infection control purposes, repeat screening of individuals in high-risk congregate settings may be useful in identifying individuals with SARS-CoV-2, thereby enabling isolation.[66]

In certain patients, the epidemiologic history may suggest other risk factors that indicate the need for specific testing, for example, for *Histoplasma* (urinary antigen), viral infections (serum antigenemia or nucleic acid testing) (Tables 122-1 and 122-8), or cryptococcal infection (serum cryptococcal antigen assay). Cryptococcal antigenemia is detectable by latex particle agglutination in patients with cryptococcal pneumonia or disseminated cryptococcal infection. Serum cryptococcal antigen detection is sensitive for the diagnosis of pulmonary infection, more so in immunocompromised than immunocompetent patients. If the clinical suspicion for cryptococcal pneumonia is high, the test should be performed. The CMV antigenemia assay detects CMV matrix protein pp65 and can be detected with use of fluorescent or peroxidase-labeled antibody staining of peripheral blood neutrophils. The assay is semiquantitative, but it is not standardized and is labor-intensive due to the liability of blood cells. The test has largely been replaced by molecular amplification methods, such as viral load measurement for detecting CMV in peripheral blood. Similar assays are available for most clinically important viruses.

Serologic Testing

Serologic (antibody) tests may be useful in establishing the cause of a variety of pulmonary infections when the causative agents are difficult to isolate. The approach requires demonstration of a fourfold or greater rise in titer between acute and convalescent samples. Serologic testing neither enables rapid diagnosis nor aids in initial selection of antimicrobial therapy. Rather, testing is useful in confirming the diagnosis in retrospect, in most instance.

Microimmunofluorescence serologic tests are of limited value in supporting the diagnosis of infections caused by *Chlamydia psittaci (psittacosis)* and *Chlamydia pneumoniae*. Similarly, for Legionnaires' disease, the indirect immunofluorescent antibody test may provide a retrospective diagnosis in epidemiologic investigations, although the antibody rise occasionally may not be demonstrable for 4 to 6 weeks after the clinical onset. Antibodies may persist for months or up to a year or more.

Cold agglutinins (IgM antibodies against I antigen on RBC membranes) develop in about half of patients with *M. pneumoniae* pneumonia, but such antibodies occur in other conditions; complement fixation testing is the preferred diagnostic procedure. For Q fever pneumonia, the complement fixation (CF) test is usually used to confirm the diagnosis, but microimmunofluorescence, microagglutination, and enzyme-linked immunosorbent assays have been used to diagnose acute *Coxiella burnetii* pulmonary infection. In acute Q fever, the phase II antibody is usually higher than the phase I titer, often by fourfold. In chronic Q fever, the reverse situation is generally seen. Tularemic pneumonia may be diagnosed serologically using an agglutination test for *Francisella tularensis*.

Serologic tests are also helpful in the diagnosis of invasive infection due to the primary pulmonary fungal pathogens. Serum IgM precipitins (latex agglutination, immunodiffusion) appear in primary coccidioidomycosis within 2 weeks of symptom onset. Abnormally high complement fixation titers (at least 1:32) are present in most patients who have disseminated infection due to *Coccidioides immitis*. Increasing complement fixation titers in serial specimens are considered diagnostic of active disease. A fourfold increase in complement fixation titer to yeast and to mycelial phases of *H. capsulatum* (or, possibly, a single titer of 1:32 or higher) and the simultaneous appearance of H and M precipitin bands on immunodiffusion test strongly suggest histoplasmosis.

Complement fixation tests for blastomycosis lack sensitivity and specificity. However, titers of at least 1:8 suggest recent or active disease, particularly if precipitins to the A antigen on immunodiffusion test also are present. In patients with suspected blastomycosis, serum antibody testing specifically directed against the anti–BAD-1 (anti–*Blastomyces* adhesin 1) antigen for blastomycosis can be used together with clinical and epidemiologic data to establish the diagnosis.[51] Sporotrichosis can be diagnosed using a serologic agglutination test when the titer is 1:8 or greater. Pulmonary toxoplasmosis is uncommon in seronegative individuals, although acute toxoplasmosis is seen in endemic regions (e.g., the Caribbean, France) following organ and bone marrow transplantation.

Serologic tests may be helpful for the retrospective diagnosis of respiratory viral infections due to influenza A and B, SARS-CoV-2, RSV, adenoviruses, and parainfluenza viruses. In a systematic review of 38 studies that evaluated the sensitivity of serologic testing by time from symptom onset in patients with COVID-19, IgM was detected in 23% by 1 week, in 58% by 2 weeks, and in 75% by 3 weeks; the corresponding detection rates for IgG were 30%, 66%, and 88%, respectively.[68] Per IDSA recommendations, serologic testing should not be used to diagnose SARS-CoV-2 infection during the first 2 weeks following symptom onset. In diagnosing COVID-19 infection in symptomatic patients with a high clinical suspicion of the infection and repeatedly negative NAAT results, SARS-CoV-2 IgG antibody or total antibody tests are preferred over IgM antibody, IgA antibody, or IgM/IgG differentiation tests because of their greater accuracy.[69]

Fungal Biomarkers

Fungal pneumonia is generally observed in the setting of anatomic abnormalities (e.g., fungus ball in a pulmonary cavity) or immune dysfunction or suppression. Cryptococcal pneumonia or disseminated cryptococcal infection may be diagnosed with high sensitivity and specificity using serum cryptococcal antigen.

Two fungal antigen tests, 1,3-β-D-glucan (BDG) and galactomannan (GM), have been developed as screening tools to assist in the detection of fungal infection in high-risk patients. Both tests are based on distinct carbohydrates found in abundance in fungal cell walls and released during invasive infections; each can be detected in BAL fluid and blood. Serum assays for BDG are recommended for diagnosing invasive aspergillosis (IA) in high-risk patients (e.g., those with hematologic malignancy or allogeneic HSCT) but are not specific for *Aspergillus*.[70] *Candida* species, while frequently isolated in respiratory specimens, rarely cause pneumonia other than in infarcted lung or as a result of embolic disease (e.g., endocarditis in injection drug users). A positive BDG assay in the immunocompromised host is likely a reflection of infection due to *Pneumocystis*, *Fusarium*, dermatophytes, and endemic fungi, in addition to *Aspergillus* spp.;[71,72] notable exceptions include *Cryptococcus* spp. and zygomycetes.[73] The sensitivity for proven or probable invasive fungal infection in various hosts is generally in the 50% to 77% range (often lower in practice) and the specificity 80% to 95%. The specificity is altered due to false-positive results from prior administration of intravenous immunoglobulin or albumin, use of cellulose hemodialysis membranes, and prior exposure to glucan-containing gauze (e.g., the packing used after surgery). BDG testing exhibits poor specificity and reproducibility in BAL; hence, assays to detect BDG typically use serum.[74]

For *Aspergillus* species, galactomannan can be measured by enzyme-linked immunoassay and has been shown to correlate with the burden of fungal disease[70–72] (Chapter 132). Serum and BAL GM are recommended as accurate markers for the diagnosis of invasive aspergillosis in adult and pediatric patients when used in select patient subpopulations (e.g., those with hematologic malignancy, HSCT).[51,70]

A meta-analysis of the performance characteristics of the assay in serum demonstrated a sensitivity of 0.71 (95% confidence interval [CI], 0.68–0.74) and specificity of 0.89 (95% CI, 0.88–0.90) using an index cutoff of 0.5 in immunocompromised patients with proven invasive aspergillosis.[75] Individual studies reveal variability in assay performance. In a meta-analysis of 16 studies involving 783 adults with hematologic malignancies, summary estimates of the overall accuracy of BAL-GM for diagnosing invasive aspergillosis were derived. BAL-GM had a reported sensitivity of 0.92 (95% CI, 0.48–0.99) and specificity of 0.98 (95% CI, 0.78–1.0) using an index cutoff of 1.5.[76] BAL-GM conferred greater sensitivity, but lower specificity, than the serum GM testing and similar specificity as the PCR assay.[76] False-positive GM results may be seen in patients undergoing chemotherapy or who are at risk for mucositis, in whom cross-reactive epitopes from other fungi or bacteria (e.g., *Bifidobacterium* spp. in neonates) may penetrate the intestinal mucosa, causing a positive test result.[51]

■ Other Tests from Nonrespiratory Specimens

High-grade bacteremia sometimes accompanies pulmonary infections, and the etiologic agent may be demonstrable on stained smears of the buffy coat of centrifuged blood. Pneumococci have been identified in Gram-stained or Wright–Giemsa–stained smears of buffy coats from a patient who has undergone splenectomy; occasionally, *M. avium-intracellulare* has been found intracellularly in acid-fast stains of buffy coats from patients with advanced HIV. Additional special microscopic examinations may be indicated for immunocompromised patients who have patchy pulmonary infiltrates on the chest radiograph. For example, the presence of the hyperinfection syndrome of strongyloidiasis (often accompanied by *Escherichia coli* bacteremia) can be established by the finding of filariform larvae in the stool suitably prepared by concentration techniques. Although eosinophilia is often present in patients with strongyloidiasis, it may be absent in the hyperinfection syndrome or in patients on corticosteroids.

■ Skin Tests of Delayed Hypersensitivity

The tuberculin skin test (TST) is of great importance in the evaluation of a pulmonary infection of unknown origin. The intermediate (5 tuberculin units) purified protein derivative (IPPD) test should be used if no information is available about previous testing. A positive test does not distinguish between prior and current infection. A negative second-strength PPD skin test in a patient who is not anergic is evidence against a tuberculous origin of a pulmonary process in a normal host. Several caveats are noteworthy: since it may take 4 to 6 weeks for the skin test to become positive, the TST may be initially negative in progressive primary pulmonary tuberculosis, and in the patient who was infected long ago, cutaneous hypersensitivity may wane. In elderly patients in whom waning has occurred, repeat testing several weeks later may show a positive result (booster effect), even if the original PPD skin test was negative. A PPD reaction of at least 5 mm is considered positive in HIV-infected patients, organ-transplant recipients, and other immunosuppressed hosts; for those with recent exposure; and in some cases of x-ray–positive, remote tuberculosis. A PPD of at least 10 mm is considered positive for individuals from an endemic region, intravenous drug users, TB laboratory personnel, group-housing residents, patients less than 5 years of age, and those with a low body weight and comorbidities that place them at high risk for TB, such as diabetes, severe kidney disease, and certain types of cancer. PPD tests should be considered positive when at least 15 mm induration in other hosts with no known risk factors for TB.[77]

Interferon-γ release assays (IGRAs) carry a 70% to 90% concordance with PPD testing and can be used in all circumstances in which TST is currently used.[78–80] The IGRA is more specific than TST, but it is more expensive and requires whole blood testing.

Fungal skin tests do not distinguish between current and past infection; indeed, active disease is often accompanied by a negative skin test. The coccidioidin skin test is the best of the available tests, but the diagnosis of coccidioidomycosis is not excluded by a negative test. Blastomycin and histoplasmin skin tests are of little value because of frequent false-negative results and cross-reactions. Also, application of the histoplasmin skin test may falsely elevate antibody levels to the *H. capsulatum* mycelial antigen.

A negative skin test response to a specific antigen must be interpreted in the light of possible anergy. A battery of control antigens (mumps, *Candida*, *Trichophyton*, streptokinase–streptodornase) serves to detect such anergy, but these reagents are increasingly unavailable and costly.

INVASIVE DIAGNOSTIC PROCEDURES

Examination of respiratory specimens should always begin with sputum examination; however, this test may not be adequate for a presumptive diagnosis in all patients. Immunocompromised patients, those on mechanical ventilation, or patients in whom there is a broad microbiologic differential diagnosis may require more invasive procedures to obtain a respiratory specimen to guide management. Such techniques avoid potential contamination of sputum samples with upper airway flora; however, they are not without risk (Chapters 33, 34, and 35).

Important considerations include the type and location of the pulmonary lesion, the ability of the patient to cooperate with the required manipulations, the presence of coagulopathies, and experience of the operator in performing the procedure. For patients who are critically ill or unlikely to tolerate invasive procedures (e.g., immunocompromised hosts, those with recent major surgery, underlying heart or liver or renal failure, or COPD), it is reasonable to consider more invasive diagnostic procedures early in the clinical course, bearing in mind the risks inherent to invasive tests. In such patients, empiric antimicrobial therapies carry the risk of obscuring a specific microbiologic diagnosis, as well as drug-associated toxicities. Such an approach may also be required if the patient's condition continues to deteriorate, despite empiric antimicrobial therapy. The selection of an invasive procedure should be based on the nature of the illness and the likelihood of success for each procedure at the institution. Imaging is also a crucial consideration, as specific procedures may be better suited for lesions in specific intrathoracic locations.

The clinician should take into account the patient's immune status and the pathogenesis of the organism under consideration when devising a diagnostic strategy. For example, *P. jirovecii* pneumonia is an alveolar process, so examination of routinely collected expectorated sputum samples for *P. jirovecii* is not often diagnostic in immunosuppressed patients without HIV. However, in patients with advanced HIV, examination of induced sputa employing aerosolized, hypertonic saline may be helpful, since the number of organisms is high in these patients. Additionally, specimens can be evaluated using a tiered approach. If results of examination of induced sputa are negative, and clinical circumstances warrant further attempts at diagnosis, follow-up bronchoscopy with transbronchial biopsy or BAL may be performed to increase diagnostic sensitivity.

■ Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy allows visualization of the tracheobronchial tree and collection of lower respiratory tract cultures through the use of protected brush catheters, bronchoalveolar lavage (BAL), and transbronchial biopsy (Chapter 33).

Endobronchial brushing involves use of a protected specimen brush, which is a brush enclosed within a catheter sheath to avoid contamination with oral flora. Insertion of a bronchoscope permits advancement of the brush out of the sheath and into the airway, allowing sampling of the involved area under direct visual guidance. After the specimen is obtained, the brush is withdrawn into its protective sheath and the sheath removed from the bronchoscope. The sample from the distal end of the brush can be sent for microbiologic testing as detailed above. Transbronchial biopsy increases the diagnostic yield and helps rule out noninfectious etiologies. It is indicated in diagnosis of pulmonary infections in the immunocompromised host and can be particularly helpful if fungal or mycobacterial infection is suspected.

BAL, performed during flexible bronchoscopy, is a method for evaluating processes at the alveolar level. This procedure involves instillation of sterile normal saline into a bronchial segment or subsegmental orifice, followed by suction and collection of the fluid for analysis. BAL allows sampling of a larger portion of the lung than transbronchial biopsy or brushing—sampling approximately 100 million alveoli.[12]

■ Diagnostic Testing in Ventilator-associated Pneumonia

Both bronchoscopic and noninvasive methods are employed for use of evaluating the lower respiratory tract in cases of suspected VAP (Chapter 129). Bronchoscopic BAL provides the highest diagnostic accuracy in diagnosing VAP. However, this requires expertise in performing the procedure and incurs risk associated with a more invasive procedure, including worsening hypoxemia and barotrauma.

Alternatives to use of BAL include the "mini-BAL" and endotracheal suctioning. The mini-BAL is performed by advancing a catheter through the endotracheal tube blindly until meeting resistance, at which time sterile saline is infused and aspirated. Mini-BAL may be used for patients in whom bronchoscopy is considered too dangerous. Endotracheal suctioning (sometimes called endotracheal aspirate) is performed by advancing a catheter through the endotracheal tube until resistance is encountered, at which time suction is applied to obtain a microbiologic specimen. Some prefer obtaining an endotracheal aspirate as the initial test in patients with suspected VAP, as this method is considered inexpensive and low risk. The ATS/IDSA 2016 Guidelines for VAP recommend use of endotracheal aspirate for diagnosis of VAP, given that it is inexpensive, provides rapid results, and is relatively lower risk than more invasive methods.[81] However, none of these methods has proved superior in diagnosing VAP, and the diagnostic approach is often dictated by institutional practices.[82]

■ Percutaneous Transthoracic Needle Lung Biopsy

Percutaneous needle biopsy, guided by radiology, is often the invasive diagnostic procedure of choice for a sizable (>1.0 cm) pulmonary nodule or cavity that is located peripherally. The small core of tissue and aspirated fluid is examined by stained smear and culture for various infectious agents. Cytologic examination should be done for neoplastic cells. Occasionally, fungal hyphae are seen. Because of the small volume of the specimen, however, histopathologic examination is generally less diagnostic. In patients with a tenuous respiratory status, or in whom lymph node biopsy or sampling of pleural fluid may be desired, video-assisted thoracoscopic surgery (VATS) or open biopsy may be preferred (Chapter 35).

■ Lung Biopsy

Open lung biopsy and VATS constitute the most definitive procedures for histopathologic diagnosis in the immunocompromised host. The procedures provide the highest yield for obtaining sufficient lung tissue for diagnosis and enable sampling of multiple sites. Surgical lung biopsy is particularly suitable for evaluating processes that may not be infectious (e.g., neoplasms, such as Kaposi sarcoma; antineoplastic drug toxicity; drug hypersensitivity; and lymphocytic interstitial pneumonia). However, the need for general anesthesia, inherent delays in preparing the patient for the procedure, the requisite intubation, the common need for placement of a chest tube, and postoperative splinting due to incisional pain may be significant challenges for the patient.

For the patient in whom the pace of the illness does not allow a sequential diagnostic approach, surgical lung biopsy may be the procedure of choice. Processing of lung biopsy specimens should include special stained imprint smears for *P. jirovecii*, bacteria (including *Nocardia* and mycobacteria), fungi, and viral inclusion bodies; cultures for bacteria, viruses, fungi, and mycobacteria; if available, NAAT for suspected organisms; and tissue sections for histology and for infectious agents.

PULMONARY INFECTIONS ACCORDING TO ETIOLOGY: VIRUSES, ATYPICAL PNEUMONIA, FUNGI, AND PARASITES

Thus far, discussion has focused on the approach to a patient with a suspected pulmonary infection and for whom a specific microbiologic diagnosis may not be known. The following discussion addresses the patient with a pulmonary infection due to a specific class of pathogen.

■ Viral Infections

Respiratory viral infections are a major cause of morbidity worldwide. Findings may occur in either the upper or lower respiratory tract. A more detailed discussion appears in Chapter 126. With upper tract disease, patients present with cough, sore throat, bronchoconstriction, fever, rhinitis, and suffusion of mucus membranes. The majority of these infections are isolated upper respiratory infections and of significance as causes of discomfort and as predisposing conditions for lower respiratory infections. Spread is via aerosolized droplets and inoculation of mucous membranes from hand contamination. The most prominent viral pathogens are rhinovirus and coronavirus, followed by adenovirus, parainfluenza virus, RSV, and influenza viruses. Less commonly, reovirus, enteroviruses, metapneumoviruses, and picornaviruses may cause the same symptoms.[83,84] Infections with respiratory viruses occur predominantly in the winter and early spring.

In considering lower respiratory infections, the most common viral pathogens include influenza, adenovirus, parainfluenza, respiratory syncytial virus, and human metapneumovirus. Viruses have the ability to undergo antigenic shift—thought to be related to interacting with animals and leading to a "jump" from animal species into humans. When antigenic shift occurs, most of the population will have little immunity to the new virus, allowing for development of a pandemic—as dramatically illustrated with the 2019 SARS-CoV-2 pandemic.

Influenza viral pneumonia usually occurs in the setting of an outbreak of influenza infections. Patients with underlying heart disease (mitral stenosis), those with chronic pulmonary disease, or those who are pregnant, as well as immunocompromised individuals, are disproportionately impacted. Unlike secondary bacterial pneumonia after influenza (a complication that occurs 1 to 4 days after improvement following typical upper respiratory illness), primary influenza pneumonia is part of the initial clinical presentation. In general, about 90% of infections are due to influenza A, and about 10% due to influenza B; variations are noted in any given year. Outbreaks of pandemic influenza (e.g., avian influenza, 2004–2007, A/H5N1) most likely arise from birds. In 2009 to 2010, the pandemic A/H5N1 was the result of avian, human, and swine influenza viruses in Mexico and was associated with significant mortality, particularly in those with underlying comorbidities, including diabetes, COPD, and obesity.

A novel Hantavirus, Sin Nombre virus, emerged in 1993 in the Four Corners area of New Mexico, Arizona, Colorado, and Utah. Although cases were reported worldwide, they occurred primarily in the west and southwestern United States.[85] The case fatality rate for the Hantavirus pulmonary syndrome is 50%.

Severe acute respiratory syndrome (SARS) is a viral respiratory illness that first appeared in southern China in 2002 before spreading globally. Its cause is a SARS-associated coronavirus (SARS-CoV). Between November 2002 and July 2003, a total of 8098 people worldwide developed SARS, and 774 died. No new cases were reported after July 2004. A related infection emerged in Saudi Arabia in 2012—Middle Eastern Respiratory Syndrome (MERS), caused by a coronavirus called MERS-CoV. MERS is a severe acute respiratory illness that presents with fever, cough, and shortness of breath following exposure in or near the Arabian Peninsula. Spread occurs by close contact, but sustained spread has not been identified. From 2012 until January 2020, the total number of deaths associated with MERS-CoV was 866 out of 2519 cases globally.[86] At the end of 2019, genomic sequencing identified a novel coronavirus SARS-CoV-2 as the cause of cluster of pneumonia cases in Wuhan, China. Infection spread rapidly, ultimately leading to the global COVID-19 pandemic.

Human metapneumovirus (HMPV) is a ubiquitous virus (Pneumovirinae subfamily, Paramyxoviridae family) that is a major cause of acute respiratory infection, particularly in children and in immunocompromised individuals. The virus has phenotypic and clinical characteristics similar to those of RSV, often presenting with bronchiolitis. The virus may coinfect individuals with other viral pathogens.

Atypical Pneumonia

Historically, so-called atypical pneumonia has been characterized as an indolent disease with a gradual onset. When referring to a bacterium as atypical, the implication is that the organism is not easily identified on routine smears (e.g., Gram stain, Ziehl–Neelsen stain) or cultures (including cultures for mycobacteria or *Legionella* species) and is resistant to β-lactam antibiotics. The syndrome was first described in the 1930s when physicians noted that a number of patients had milder symptoms than patients with the "typical" presentation attributed to *S. pneumoniae*, *H. influenzae*, *S. aureus*, and gram-negative rods.[87] Typically, the patient's cough is described as "dry," with minimal sputum production. Extrapulmonary symptoms, such as malaise, headache, and myalgias, are frequently reported.

TABLE 122-9 Causes of "Atypical Pneumonia"

Mycoplasma	
	M. pneumoniae
Chlamydophila	
	C. psittaci (psittacosis), *C. pneumoniae*
Bacteria	
	Legionella spp., *F. tularensis*, *Y. pestis*, *B. anthracis (agents of bioterrorism)*
Fungi	
	Histoplasma, *Blastomyces*, *Coccidioides*, *Pneumocystis*
Aspiration pneumonitis	
	Sterile or mixed upper respiratory and oral flora
Viral agents	
	Respiratory tract viruses: influenza, adenovirus, respiratory syncytial virus (RSV), parainfluenza virus, metapneumovirus
	Varicella-zoster, measles, Epstein–Barr virus (EBV), cytomegalovirus (CMV), Hantavirus
Rickettsia	
	C. burnetii (Q fever)

The etiologies of atypical pneumonia are heterogeneous and include bacteria, viruses, and fungi (Table 122-9). *M. pneumoniae* is the most common pathogen associated with atypical pneumonia and accounts for up to 15% of cases treated on an outpatient basis.[88] In adults, *M. pneumoniae* pneumonia often begins insidiously with malaise, fever, and prominent headache. Sore throat is common, but coryza is minimal or absent. Nonproductive cough, developing over a few days, is the hallmark of the disease. Small outbreaks of *M. pneumoniae* infection in households, schools, and military camps may not be appreciated because of the long incubation period and variation in clinical presentation.

Legionella accounts for 1% to 10% of cases of community-acquired pneumonia and is notable given its ability to cause severe disease that frequently necessitates care in an intensive care unit.[4,25,89] Respiratory viruses are responsible for another 30% of cases and should be considered in the initial evaluation. *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Coxiella burnetii*, *Francisella tularensis*, *Yersinia pestis* (plague pneumonia), *Bacillus anthracis* (anthrax pneumonia), and endemic mycoses have all been described as causes of community-acquired pneumonia, albeit less frequently than the agents previously noted.

Fungal Pneumonia

Fungal pneumonia occurs most often in immunocompromised hosts. In the normal host, infection due to the endemic or geographic fungi (i.e., *Histoplasma capsulatum*, *Coccidioides immitis*) or to *Cryptococcus neoformans* may be asymptomatic or present with systemic signs. The diagnosis is often confused with acute bronchitis, viral infection, mycobacterial infection, or aseptic meningitis. Otherwise, fungal infection of the lungs is most commonly associated with anatomic defects (e.g., aspergilloma in a pulmonary cavity); it is otherwise rare in individuals without immune defects.

Pneumocystis jirovecii causes pneumonia in immunocompromised individuals, particularly those on corticosteroids. Hypoxemia is prominent and often accompanied by few physical or radiologic findings. As this infection is easily prevented, consideration should be given to prophylaxis in any individual receiving chronic immunosuppressive therapy, or who has HIV infection or AIDS unresponsive to antiretroviral therapy.

Traditionally, aspergilloma has been considered to represent noninvasive colonization of pulmonary cavities, although gross hemoptysis may complicate management, and dissemination may occur at the time of surgical resection. Immunosuppression may convert benign disease into invasive infection. Aspergillosis is among the more common and aggressive pneumonias seen after bone marrow and organ transplantation.

Mucormycosis (due to the *Mucoraceae*) causes rapidly progressive sinus and lung infection that requires surgical resection for cure. This infection is most common in diabetics and other immunocompromised hosts. Fusarium species typically disseminate via the bloodstream, producing diffuse pulmonary infiltrates that are often accompanied by skin lesions (Chapter 123).

■ Endemic Mycoses

The principal clues to the presence of pulmonary mycoses are epidemiologic (Chapter 133). The principal endemic areas for histoplasmosis are in the midwestern United States, Central and South America, and Africa. Disease may be found in other locales and after travel. The organism is present in high concentrations in soil sites where avian, chicken, or bat excrement has accumulated. Movement of soil in such endemic areas by cleaning chicken coops or bird roosts, in old attics, or caves may expose people to high concentrations of airborne spores that, when inhaled, produce an acute pneumonia.

Blastomycosis is endemic in the southeastern United States, and regions of note extend north into eastern Canada. Rural exposure to soil contaminated with animal excrement appears to be a risk factor. Skin lesions, either verrucous or ulcerative, are the most common extrapulmonary manifestations of blastomycosis and offer a clinical clue to diagnosis (Chapter 27).

Coccidioidomycosis is endemic in the southwestern United States (California, particularly the San Joaquin Valley, and Arizona) and in neighboring portions of Mexico. Infection is usually acquired in these areas by inhalation of highly infectious arthrospores. Occasionally, major dust storms carry the arthrospores considerable distances from their soil source and produce unexpected outbreaks of infection. Archeologic digs sometimes cause infection in those living elsewhere who have received an artifact uncovered in the explorations. Erythema nodosum may be associated with any of the primary pulmonary mycoses, but most often with coccidioidomycosis. The coincidence of this hypersensitivity skin lesion and an atypical pneumonia syndrome in a person from an endemic area suggests the possibility of one of these pulmonary mycoses.

Paracoccidioidomycosis (South American blastomycosis) is endemic to Brazil and is found in Colombia, Venezuela, and Argentina. The disease is caused by *Paracoccidioides brasiliensis*. In adults, the manifestations of the disease are mainly pulmonary; radiographs show patchy or confluent areas of consolidation, often bilateral. Cases have occurred in North America and Europe, but in those instances, the patients had previously resided in endemic areas where initial infection presumably had been acquired.

■ Parasitic Pneumonia

Parasitic pneumonias are rare and require endemic exposures (Chapter 135). Pneumonias occur when the organism lifecycle includes the lungs. Pulmonary infections due to migrating worms include Loeffler-like syndrome with *Ascaris lumbricoides*; post-obstructive pneumonitis and polymicrobial systemic sepsis and meningitis due to *Strongyloides stercoralis*; cysts and nodules due to *Echinococcus granulosus*, *Paragonimus westermani,* and *Schistosoma* species; and pulmonary eosinophilia with filariasis. Infection by *Entamoeba histolytica* causes pleuropulmonary disease as a result of (1) *sympathetic* reaction to an unruptured abscess within the liver; (2) empyema, after rupture of the liver abscess into the pleural space; or (3) parenchymal involvement with abscess, consolidation, or hepatobronchial fistula after the rupture of a liver abscess.

Acute infection due to *Toxoplasma gondii* in the immunocompetent host is generally asymptomatic, with cervical lymphadenopathy as the hallmark of disease. It may be confused with mononucleosis caused by Epstein–Barr virus or CMV. Fever, malaise, sore throat, and hepatosplenomegaly also are seen, and the peripheral blood may manifest atypical lymphocytosis. Rarely, acute disease may present with severe dissemination, marked by pneumonitis, hepatitis, encephalitis, polymyositis, or myocarditis.

FAILURE OF THERAPY

Nonresolving pneumonia may be a result of inappropriate antibiotics, superinfection, inadequate host response, airway obstruction, empyema, noninfectious processes, or recurrent infection.[90] Inappropriate antimicrobial therapy includes inadequate dosing, use of agents that fail to penetrate infected lung tissue (e.g., aminoglycosides or daptomycin), or use of agents to which the organisms are resistant.[91] Common examples of resistance include use of a β-lactam, such as amoxicillin in the case of β-lactamase–producing *H. influenzae*; use of azithromycin or doxycycline for resistant *S. pneumoniae;* or infection with *Pseudomonas* or MRSA, which are not adequately treated with empiric regimens for outpatient CAP. Failure to respond could represent progression of a viral pneumonia to bacterial superinfection, often with MRSA. Empyema or loculated infection may evolve during appropriate therapy for pneumonia. Relapsed infection is common in intubated patients colonized with resistant microorganisms. Unresolving pneumonia may also result from infections with mycobacteria (*M. tuberculosis* and nontuberculous mycobacteria), endemic mycoses (*Blastomyces dermatitidis*, *Histoplasma capsulatum*), or less common bacteria, including *Nocardia* and *Actinomyces israelii.* These infections are more difficult to diagnose and treat. *Nocardia* and *Aspergillus* should be considered in the immunosuppressed host. Untreated endovascular infections, intraabdominal abscess, or septic pulmonary emboli may cause persistent, evolving lung infections.

In the immunocompromised host, reduction of exogenous immunosuppression, repletion of antibodies through the use of intravenous immunoglobulin, normalization of low neutrophil counts (via use of colony-stimulating factor), treatment of concomitant viral infections (HIV, CMV), and repeat culturing may assist in management. Airway obstruction or empyema must be addressed to promote source control and resolution of infection. Recurrent infection may be observed when there are mechanical issues at play, for example, if there is ongoing aspiration or sinusitis, if the patient has a misplaced feeding tube or has airway narrowing, or if a pulmonary embolism with infarction has occurred. Additional cultures and radiologic studies (e.g., CT scans) may assist in defining lung processes failing to respond to therapy. Bronchoscopic evaluation and, in selected patients, lung biopsy also may assist in further diagnosis and management.

NONINFECTIOUS PROCESSES MIMICKING PULMONARY INFECTIONS

The list of noninfectious disorders that mimic pulmonary infections is extensive (Table 122-10). These diagnoses should be considered

TABLE 122-10 Noninfectious Causes of Febrile Pneumonitis Syndrome (Mimics of Pulmonary Infection)

- Drug-induced pulmonary disease
- Hypersensitivity pneumonitis
- Injury due to inhaled toxic gases, dusts, chemicals
- Acute eosinophilic pneumonia
- Chronic eosinophilic pneumonia
- Interstitial lung disease associated with autoimmune/connective tissue disorders
  - Systemic lupus erythematosus
  - Polymyositis–dermatomyositis
  - Mixed connective tissue disease
- Interstitial lung disease associated with pulmonary vasculitis
  - Granulomatous polyangiitis (formerly known as Wegener granulomatosis)
  - Lymphomatoid granulomatosis
  - Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
  - Polyangiitis overlap syndrome
- Interstitial lung disease associated with airway disease
  - Allergic bronchopulmonary aspergillosis
  - Bronchocentric granulomatosis
  - Bronchiolitis obliterans (OB) and bronchiolitis obliterans with organizing pneumonia (BOOP)
- Acute or subacute interstitial pulmonary fibrosis (AIP)
- Idiopathic interstitial pneumonia
  - Usual interstitial pneumonia (UIP)
  - Nonspecific interstitial pneumonia (NSIP)
  - Desquamative interstitial pneumonia (DIP)
  - Respiratory bronchiolitis interstitial lung disease (RB-ILD)
  - Acute interstitial pneumonia (AIP)
  - Cryptogenic organizing pneumonia (COP)
  - Lymphoid interstitial pneumonia (LIP)
- Pulmonary neoplasms
- Sarcoidosis
- Pulmonary infarction
- Acute chest syndrome in sickle-cell crisis
- Radiation pneumonitis
- Lipoid pneumonia (exogenous or endogenous)
- Acute respiratory distress syndrome (ARDS)
  - Extrapulmonary sepsis
  - Oxygen toxicity, chemical inhalation or aspiration, or aspiration of gastric contents
  - Pancreatitis
  - Fat embolization (surgery, trauma)
  - Shock of various etiologies
  - Drug overdose (aspiration)
  - Chest trauma
- Transfusion-related acute lung injury (TRALI)
- Pulmonary alveolar proteinosis
- Plasma cell granuloma
- Eosinophilic granuloma
- Idiopathic pulmonary hemosiderosis
- Goodpasture syndrome—GBM disease
- Miscellaneous

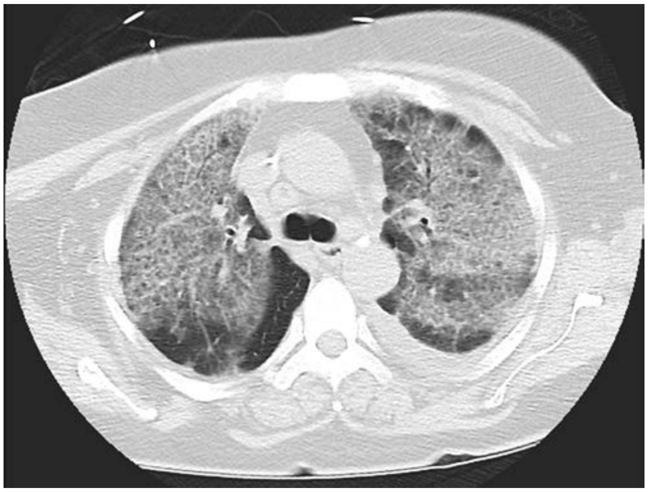

Figure 122-13 Bilateral ground-glass opacities on computed tomography in patient eosinophilic pneumonia. *(Reproduced with permission from Dr. M. Kavanaugh.)*

in the course of taking the initial history and reviewed again if the initial diagnosis does not improve with seemingly appropriate treatment.

The likelihood of noninfectious etiologies of pulmonary disease increases if the Gram-stained smear and culture of sputum are unrevealing, if the initial response to empiric antimicrobial therapy proves unsatisfactory, or if radiographic findings are atypical. Similar histologic appearances result from both infectious and noninfectious etiologies. The presence of a maculopapular skin rash, generalized lymphadenopathy, joint or rheumatologic symptoms, or peripheral eosinophilia should suggest hypersensitivity or a rheumatologic etiology, such as eosinophilic pneumonia (Fig. 122-13).

As noninfectious and infectious processes often coexist, it is essential to exclude infectious causes of pulmonary dysfunction before treating. Immunosuppressive agents, notably corticosteroids, will reduce inflammation due to both infectious and noninfectious causes, and may contribute to progression of untreated infection. Noninfectious etiologies such as sarcoidosis, granulomatosis with polyangiitis, or pulmonary emboli may masquerade as a respiratory infection. A chest radiograph of a patient with sarcoidosis is shown in Fig. 122-14. Findings could be mistaken for an infectious process on initial evaluation. Patients who present repeatedly with symptoms suggestive of pneumonia that do not improve with antibiotics should be evaluated for noninfectious processes.

CONCLUSION

Pulmonary infections include a broad array of disease entities with varying degrees of severity. This chapter provides a general approach to caring for a patient with a suspected pulmonary infection. Successfully diagnosing and treating a patient with pneumonia requires a thorough history and physical examination, as well as obtaining multiple diagnostic studies to better characterize the underlying pathology. Radiographs allow the practitioner to assess the severity of pneumonia and to distinguish this process from acute bronchitis. Unfortunately, no radiographic findings are specific enough to define the microbial origin of a given pneumonia or pulmonary infiltrate. The only definitive way to obtain a specific etiologic diagnosis is through demonstration of the infecting organism. With varying sensitivity and specificity, this can be achieved by examination of stained smears of sputum and pleural fluid or other biologic materials, culturing respiratory secretions and blood, demonstrating nucleic acids or proteins from an infecting microorganism, or demonstrating an increase in antibody titer against

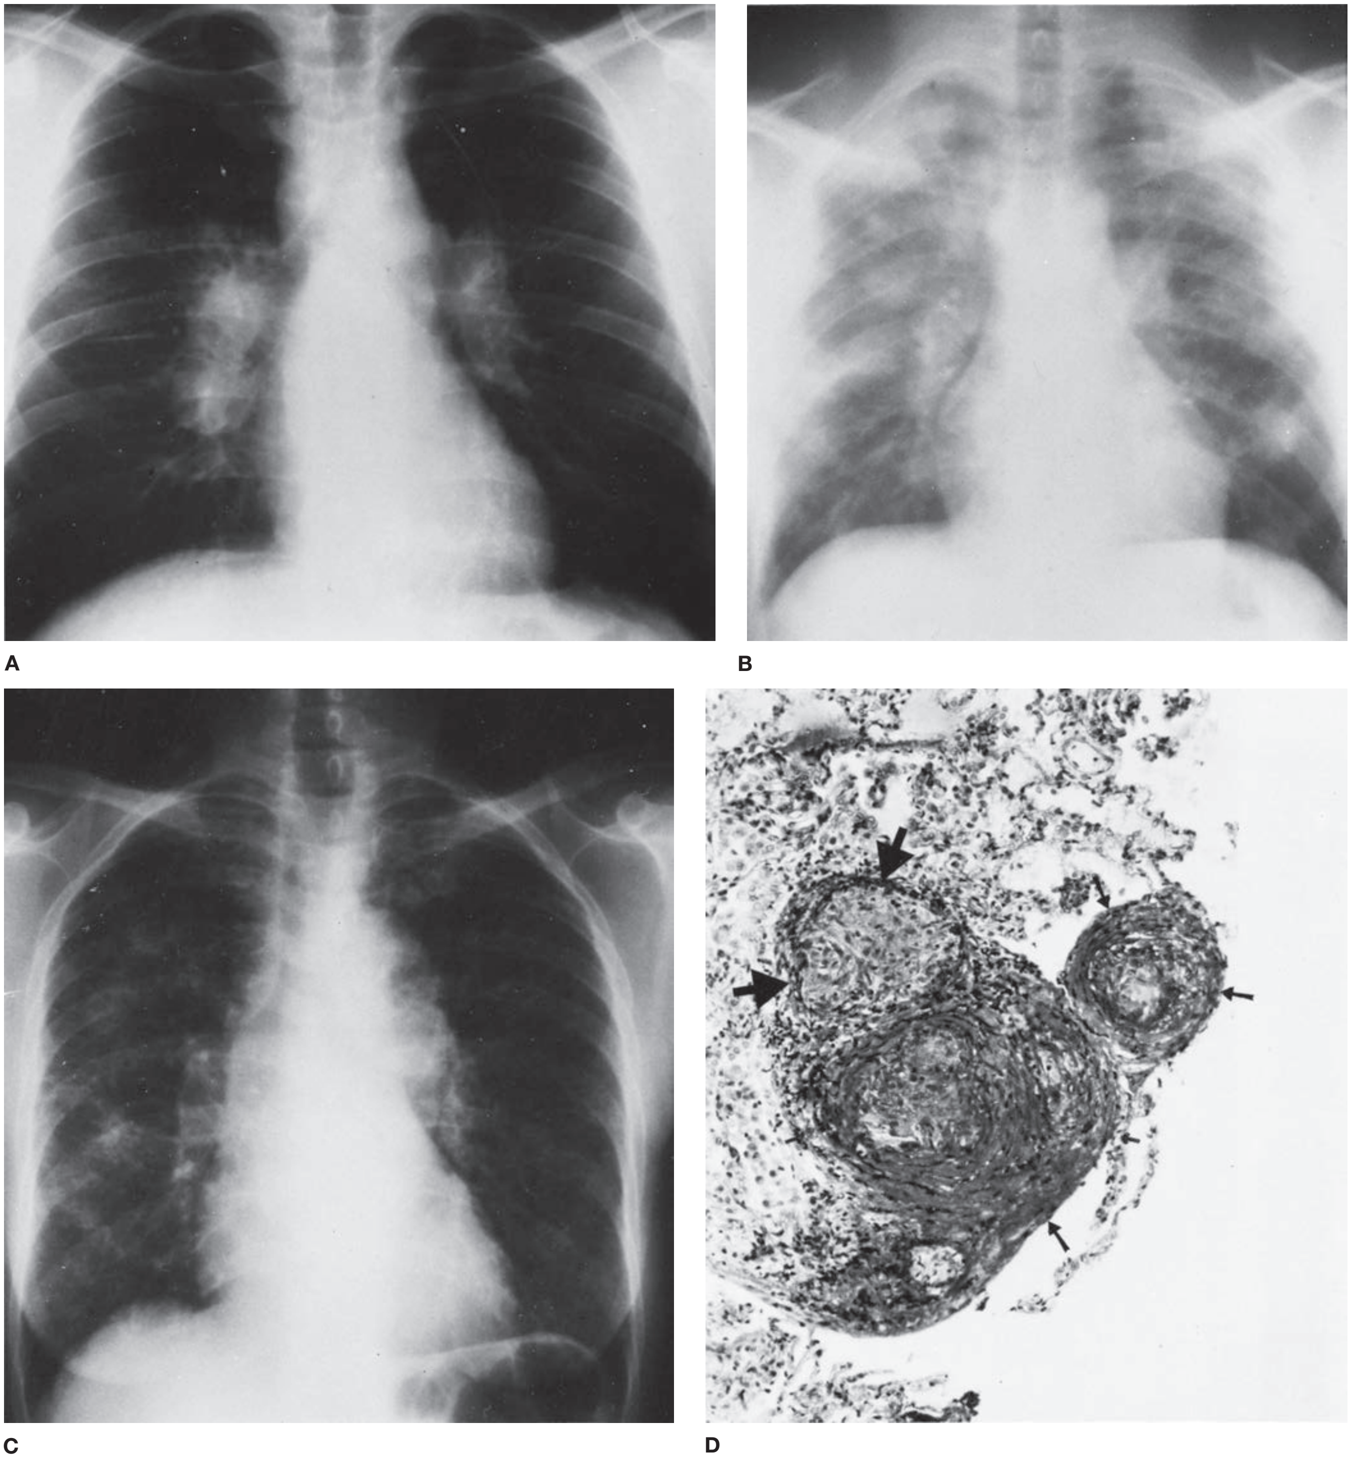

Figure 122-14 **A–C.** Chest radiographs illustrating the various stages of sarcoidosis. **A.** Stage I, bilateral hilar adenopathy. **B.** Stage II, bilateral hilar adenopathy with parenchymal infiltrates. **C.** Stage III, parenchymal infiltrates without hilar adenopathy. **D.** Transbronchial lung biopsy from a patient with sarcoidosis. *Small arrows* indicate granuloma with a surrounding rim of collagen (confirmed by positive trichrome staining). The *large arrows* indicate a granuloma without a surrounding rim of collagen. Original magnification ×10.

the infecting microorganism. Notably, these microbiologic studies are recommended only for severely ill patients, immunosuppressed patients, or those being started on antibiotics for resistant organisms (such as MRSA and *Pseudomonas*). Often, the microbiologic etiology is not identified at the time of presentation, and treatment must be initiated empirically. It is important to follow the patient's clinical arc, changing antibiotics if necessary, and discontinuing them when an alternative diagnosis becomes more apparent. Ultimately, pulmonary infections are among the most common and serious challenges a clinician will face. Having a solid framework for obtaining information and synthesizing a clinical plan to facilitate swift action when caring for these patients is crucial.

ACKNOWLEDGMENT

This manuscript was modified from the prior edition written by Jay A. Fishman, MD.

Special thanks to Mikey Kavanaugh, MD, for providing illustrative computed tomography images. We are so appreciative of the

numerous microbiology technicians for their scientific excellence and integral contribution to providing clinical care. In particular, we acknowledge the patients who have perished due to COVID-19 and the front-line providers with whom we stand shoulder-to-shoulder in the face of this grim pandemic.

Camille Nelson Kotton

OVERVIEW

Immunocompromised host is a term encompassing a growing group of individuals with a variety of immunocompromising conditions and varying degrees of immunodeficiency.[1] The group includes persons with human immunodeficiency virus (HIV), solid organ transplant (SOT) recipients, hematopoietic stem cell transplant (HSCT) recipients, those on chemotherapy for malignancies, those receiving medications for autoimmune conditions, those with primary immune deficiencies, and those with acquired or intrinsic immune deficiencies.

This large and diverse group is expanding as medical therapies improve and evolve. Similarly, the medical complexity of the immunocompromised host is rising with new therapeutic agents, use of immunosuppressive agents later in life as immunosenescence occurs,[2] and prolonged survival of immunocompromised individuals. This prolonged survival is frequently due to improved management of infectious complications of immunodeficiency.[3]

Pulmonary infections encompass a major category of infectious complications affecting these individuals.[4–8] Pulmonary infections in immunocompromised hosts have a spectrum beyond that of immunocompetent hosts, with greater variety of presentations and the potential for both multiple infections *and* noninfectious processes to occur simultaneously. Opportunistic infections (those infections that do not usually occur in immunocompetent individuals, or that do so with increased virulence) are an important group of infections in immunocompromised hosts, but common or "typical" infections continue to constitute the majority of infections occurring in immunocompromised hosts, albeit often with more severe or prolonged manifestations.

While some infections are more common with specific immune deficits (Table 123-1), this is not always the case. Similarly, many patients have multiple simultaneous immune deficits, making an immune deficit approach alone inadequate for clinical management.

This chapter aims to provide an adjunct to the preceding chapter on pulmonary infection in the immunocompetent host (Chapter 122) in order to provide a framework with which clinicians can approach the wide variety of presentations immunocompromised patients with possible pulmonary infection may have, rather than specific details about individual disease states or infection, which can be found in later chapters of this text.

GENERAL PRINCIPLES OF MANAGEMENT OF OPPORTUNISTIC INFECTION

Opportunistic infection is defined as infection occurring as a result of compromised immune function and that would not be expected to occur, or would otherwise cause disease of lesser intensity in the presence of normal immune function. Thus, immunocompromised individuals are subject to infections commonly present in the community; however, these infections are likely to be of greater frequency or severity than in the immunologically normal host. In addition, infection in these patients may be caused by organisms of low native virulence or that cause insignificant disease in the normal host, including such organisms as *Pneumocystis jirovecii* or cytomegalovirus (CMV).

The risk of infection in any patient is determined by the interaction of two factors: the potential pathogens to which the individual is exposed (epidemiologic exposures), and a measure of

TABLE 123-1 Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia/ neutropenia	Leukemia, cytotoxic chemotherapy, HIV, drug toxicity, Felty syndrome	Enteric Gram-negative bacteria, *Pseudomonas*, *S. aureus*, *Staphylococcus epidermidis*, streptococci, *Aspergillus*, *Candida*, other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin disease, trauma (burns), lazy leukocyte syndrome, CT disease	*S. aureus*, *Candida*, streptococci
Neutrophil killing	Chronic granulomatous disease, myeloperoxidase deficiency	*S. aureus*, *E. coli*, *Candida*, *Aspergillus*
T-cell defects	HIV, congenital, lymphoma, sarcoidosis, viral infection, HSCT, solid-organ transplants, steroids, purine analogues (fludarabine)	Intracellular bacteria (*Legionella*, *Listeria*, mycobacteria), HSV, VZV, CMV, EBV, parasites (*Strongyloides*, *Toxoplasma*), fungi (*P. jirovecii*, *Candida*, *Cryptococcus*)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, acute lymphocytic leukemia, use of anti-CD20 agents (e.g., rituximab)	*S. pneumoniae*, *H. influenzae*, *Salmonella* and *Campylobacter* spp., *Giardia lamblia*, Gram negative (*E. coli*, skin)
Splenectomy	Surgery, sickle-cell anemia, cirrhosis, use of eculizumab	Encapsulated bacteria (*S. pneumoniae, H. influenzae, N. meningitidis*), *Salmonella* spp., *Capnocytophaga canimorsus*
Complement	Congenital/acquired defects	*S. aureus*, *Neisseria* spp., *H. influenzae*, *S. pneumoniae*, *Capnocytophaga*
Anatomic defects/ compromise	Intravenous or urinary catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

the individual's susceptibility to infection, termed the "net state of immunosuppression" (Table 123-2).[9–11]

The occurrence of infection in an individual at a time when the immune status of the patient is thought to be nearly normal is evidence that either an excessive environmental exposure has occurred or that the immune status of the individual is depressed. Conversely, even minimal environmental exposures may cause invasive infection in an individual who is maximally immunosuppressed.

Several key concepts help guide the approach to pulmonary infection in the immunocompromised host:

- The combination of epidemiologic exposures and net state of immunosuppression provides guidance as to the spectrum of pathogens that many be encountered.
- The timing of illness onset relative to commencement of the immunocompromised state can be a useful guide to likely infection in some hosts, such as those with HIV, solid organ transplant recipients, bone marrow transplant recipients, and those receiving chemotherapy for cancer.
- Clinical and radiographic features at presentation are often vague or atypical compared with immunocompetent hosts.
- Specific and accurate microbiologic diagnosis is essential for diagnosis and successful management.
- Immune reconstitution syndrome can occur with institution of antimicrobial therapy or reduction in immunosuppressive state.
- Multiple infectious and noninfectious processes can occur simultaneously in immunocompromised hosts.

■ The Net State of Immunosuppression

The *net state of immunosuppression* (Table 123-2) is a conceptual framework for the host factors that contribute to infectious risk.[10] These include the dose, duration, and temporal sequence in which immunosuppressive drugs are deployed; injuries to the primary mucocutaneous barrier to infection (e.g., indwelling catheters and drains); leaks and fluid collections (hematoma, effusions, ascites); ischemic tissues; surgical anastomoses; neutropenia or lymphopenia; underlying immunodeficiency; pulmonary aspiration injury; metabolic problems including protein–calorie malnutrition, uremia, and hyperglycemia; and infection with immunomodulating viruses (CMV, Epstein–Barr virus [EBV], hepatitis B and C, influenza, and human immunodeficiency virus [HIV]). These viruses predispose to other opportunistic infections and also to graft rejection and to graft-versus-host disease (GVHD). Foreign materials (e.g., vascular grafts, heart valves, sutures) provide a nidus for infection for an organism that would not be capable of causing infection under normal conditions.

The sum of the congenital, metabolic, medication, and surgery-related factors is the patient's net state of immunosuppression.[10] Generally, more than one factor is present in each host; the identification of the relevant factors, and correction when possible, is central to the prevention and treatment of infection in these hosts. For example, in the lung transplant recipient with CMV infection and thoracic fluid collections, the net state of immunosuppression includes the immunosuppression used to maintain graft function; diminished immunologic responsiveness due to CMV; the risk of empyema and bacteremia from fluid collections at surgical sites; exposure to, and colonization with, community-acquired and nosocomial organisms; and new infections (e.g., aspiration, *Clostridium difficile* colitis) that may occur during the prolonged waiting period for a compatible organ. When the organ for transplantation becomes available, it may carry latent infection (e.g., CMV, EBV, *Mycobacterium tuberculosis*) or organisms acquired by the donor during hospitalization (e.g., bacteremia) or procurement. The recipient is often critically ill and is subjected to a major surgical procedure. After surgery, the lungs are apt to be compromised, recovery of function in the allograft is often slow, immunosuppressive drugs are initiated, intravenous and urinary catheters and drains are placed, and major incisions need to heal. Drug toxicities are common and may result in renal dysfunction, confusion, or neutropenia. The sum of the underlying, operative, medication, and transplant-related factors is the net state of immunosuppression.

Pulmonary defense mechanisms are compromised to varying degrees in immunocompromised hosts (Chapter 122). Structural defects (fibrosis, airway or lymphatic obstruction by tumor, emphysema) interfere with normal clearance mechanisms. Clearance mechanisms are further impaired by excess mucus and ciliary defects, as in cystic fibrosis, congenital defects, and after lung transplantation, including those due to recent viral or bacterial infections. For example, *Mycoplasma* shears off epithelial cilia, incapacitating the mucociliary elevator.[12] Viral infections may immobilize pulmonary macrophages (CMV), produce local or systemic immunosuppression, and disrupt the local cytokine network.[13] These effects are amplified in the lung transplant recipient in whom the impact of systemic immunosuppression is added to the possible effects of tracheal anastomotic narrowing and tissue ischemia, an impaired cough reflex, progressive bronchiolitis obliterans syndrome, decreased pulmonary T-cell and macrophage functions, hypogammaglobulinemia, and disrupted lymphatic drainage. Thus, in the solid-organ transplantation recipient, the immunosuppression used to prevent graft rejection, as well as technical factors, the diminished host immune responses in the major histocompatibility–mismatched organ, and the impact of immunosuppressive viral infections are the main mediators of susceptibility to infection.

In the stem cell recipient, the intensity of immunosuppression varies with the degree of histocompatibility mismatch between donor and recipient. Nonmyeloablative regimens have reduced the duration of the initial period of neutropenia. Susceptibility

*Multiple conditions and infections occur in each host. The risk of infections or conditions from early in the course of disease will persist without specific therapy or prophylaxis. *Mycobacterium* tuberculosis may occur at any point in the continuum. HIV-2 may have slower progression than HIV-1.

Figure 123-1 Timeline of infections in untreated HIV with typical CD4+ T-cell count.

to infection in both autologous and allogeneic HSCT recipients, however, persists despite immune reconstitution.[14] Innate immune function is reduced early (first 6 months) as NK cells and alveolar macrophages suffer dysregulation of cytokine, eicosanoid (leukotrienes, prostanoids), and intracellular signaling, and alterations in scavenger receptors, resulting in reduced phagocytosis and bacterial and fungal killing. Over time, persistent reductions are observed in multiple T- and B-cell lineages and maintained in the setting of chronic GVHD.[15] T-cell functions are suppressed by the immunosuppressive agents used to prevent or treat GVHD.

The Timeline of Infections

Certain immunocompromising states have a "typical" timeline of infections that have been well characterized and are an important clinical tool when evaluating these patients.[14,16,17] With standardized immunosuppressive and chemotherapeutic regimens, specific types of infections often occur in a predictable pattern as a reflection of the specific risk factors present at each phase of the immunosuppressed state. This is best illustrated in patients with HIV (Fig. 123-1) and patients who have had HSCT or SOT (Fig. 123-2). These timelines are altered by specific immunosuppressive regimens, use of antimicrobial prophylaxis, and individual factors (e.g., underlying immune deficits, microbial colonization, organ dysfunction, epidemiologic exposures), but they are useful in considering the "likely" etiology of infectious syndromes in immunocompromised hosts.[5,14]

Timelines (Figs. 123-1 and 123-2) are used in a number of ways:

- To develop a *differential diagnosis* for infectious syndromes by time posttransplant—what type of infections are most likely at various times after transplantation.
- To develop prophylactic strategies for each patient population based on general considerations (e.g., duration of neutropenia or of T-cell defects) and patient- or institution-specific patterns (e.g., microbial resistance, drug allergies).
- To identify *excess epidemiologic hazards*, including *nosocomial hazards*—for example, *Aspergillus*, methicillin-resistant *Staphylococcus aureus,* and vancomycin-resistant enterococci, which may be clustered in time and space, by inpatient unit, by procedures, or by surgical suite; *community exposures*—for example, respiratory viruses, *Legionella*, other outbreaks (SARS-CoV-2); and *individual risks*, including unique exposures (e.g., hobbies), travel, and occupational hazards.
- *To assess excessive immunosuppression*—too many infections or unusual severity and/or at the wrong time on timeline suggesting that a problem exists with routine immunosuppressive regimens.

The patterns are altered by antimicrobial prophylaxis, antiviral therapies for HIV, CMV, and hepatitis B and C viruses, the broader range of immunosuppressive and chemotherapeutic agents, and the use of nonmyeloablative conditioning regimens for HSCT. However, the general concepts and major determinants of infection remain the same: the epidemiology of the patient and the intensity of immunosuppression coupled with mucosal injuries and other individual risk factors. Superimposed viral infections will increase the risk of opportunistic infection at any point along the timeline.

In immunocompromised hosts, the risks of infection may be *relatively stable* over time, as in the diabetic with vasculopathy and neuropathy who is prone to skin and soft tissue infections. The risks of infection may be *time-limited*, as in the postsurgical patient without complications. The risk of infection may be *cumulative and progressive*, as in the untreated patient with HIV, in whom infection is a function of declining immune function and immune memory, falling CD4+ lymphocyte counts, rising viral loads, and the effects of persistent infections (CMV, *Cryptosporidium*) (Fig. 123-1).[17,18] In these individuals, the occurrence of new types of infection suggests the progression of immunocompromise.

The risks of infection may also *change predictably with time* as a function of relatively standardized immunosuppressive regimens

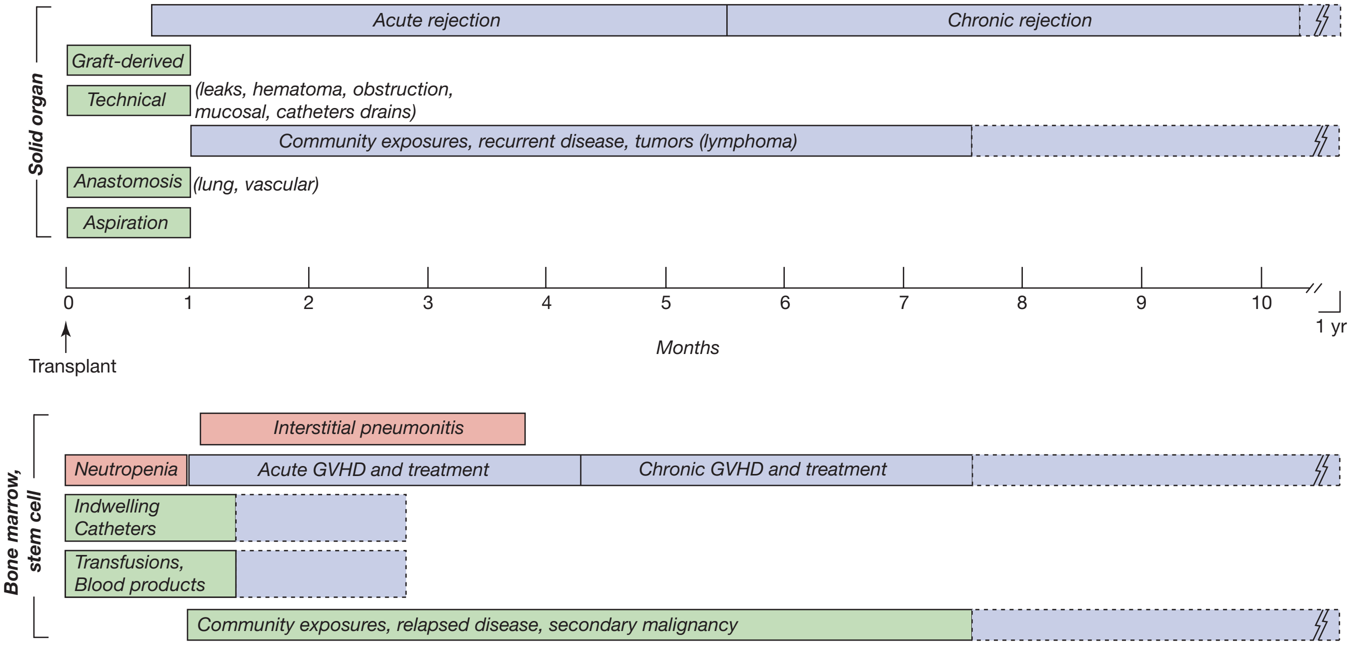

Figure 123-2 The timelines of conditions predisposing to infection in solid-organ transplantation *(above the timeline)* and in bone marrow and stem cell transplantation *(below the timeline)*. Patients vary in individual susceptibility patterns and with regard to prophylactic therapies.

and the evolving condition of the patient, as in allogeneic HSCT or solid-organ transplantation.[14,16] For example (Fig. 123-2), in the early phase after HSCT or the "pre-engraftment phase," the risk for infection is driven by neutropenia and mucositis and is generally related to nosocomial or endogenous exposures (Gram-negative and Gram-positive bacteria, *Candida* and *Aspergillus* species).[19] With nonmyeloablative preparative regimens, this period is generally 14 to 21 days, but it may be significantly longer. This reflects microbial colonization, pre-existing infections, and the impact of vascular access catheters, as well as defects in innate immune function and in mucosal barriers. Subsequently, following marrow engraftment (the "early post-engraftment phase" lasting approximately 3 weeks to 3–6 months), with continued immunosuppression and the absence of full cellular immune function, viral infections predominate, including pneumonitis or colitis (herpes, shingles, CMV, respiratory and enteric viruses), as well as encapsulated bacteria, *Pneumocystis*, and *Aspergillus*.[14] In this period, unusual infections (toxoplasmosis) and endemic pathogens also must be considered. Thus, "common" pathogens might be dengue virus and *Mycobacterium tuberculosis* in Southern Asia, or *Paracoccidioides* and *Mycobacterium tuberculosis* in Brazil. Full immune recovery is not achieved before 12 to 24 months, and gaps in immune function may persist for longer periods. During the development of and treatment for acute and chronic GVHD, susceptibility to infection is a function of the intensity of immunosuppression and mucosal injuries (from GVHD, chemotherapy, radiation, or infections such as *C. difficile* colitis). In patients with GVHD in particular, bronchiolitis obliterans, posttransplant lymphoproliferative disorders, and idiopathic pneumonitis syndrome may be observed.[20] Nonmyeloablative conditioning has reduced the rate of diffuse alveolar hemorrhage (early), hepatic veno-occlusive disease, and idiopathic pneumonitis syndrome.[20]

In the solid organ transplant recipient, immunosuppression is most often continued for the life of the transplanted organ. Early (first month) nosocomial infections (surgical and nosocomial) and donor-derived infections are observed, but opportunistic infections are not generally seen as the full impact of immunosuppression is not yet appreciated.[16] After a month, as the effects of immunosuppression are maximized, viral infections predominate (CMV, EBV, other herpesviruses, BK polyomavirus, respiratory viruses), and opportunistic pathogens (*Nocardia*, *Toxoplasma*, *Cryptococcus*, *Pneumocystis*, mycobacteria, and endemic species) are observed.[16] The endemic species include community-acquired infections, such as geographically restricted fungi (*Histoplasma*, *Coccidioides*, *Blastomycosis*, *Paracoccidioides*) and parasites (*Trypanosoma cruzi*, *Leishmania*, *Strongyloides*).

Because each risk factor renders the patient susceptible to infection by new groups of pathogens, infections occurring with the "wrong" pathogen or at the wrong time suggest an undiscovered "immune deficit" (fluid collection, neutropenia) or an unusual epidemiologic exposure (Table 123-1). The occurrence of specific infections can be prevented by the use of antimicrobial prophylaxis, vaccines, and behavioral modifications (e.g., no raw vegetables or digging in gardens without masks). This may result in a "shift to the right" of the timeline in that infections are delayed but incompletely prevented unless the intensity of immunosuppression is reduced.[5,16]

PREVENTION OF PULMONARY INFECTION

A key requirement for clinicians prescribing immunosuppression is consideration of whether screening and/or treatment for latent or active infection are required *prior* to immunosuppression and whether antimicrobial prophylaxis needed. When there is uncertainty, consulting an expert or a consensus guideline will often provide useful tools to guide the clinician. Consideration must also be given that guidelines cannot cover all scenarios and at times. For instance, a patient with systemic lupus erythematosus on hydroxychloroquine and 15 mg of prednisone would not usually reach a threshold in most guidelines to require *Pneumocystis* prophylaxis. However, should that patient develop new lupus nephritis, require dialysis, and commence cyclophosphamide then the "net state of immunosuppression" has changed, and *Pneumocystis* prophylaxis should be reconsidered.

Given the often predictable occurrence of many infections in particular hosts, for example *Pneumocystis* in people with HIV and CD4+ counts below 200 cells/μL, the potential to prevent infection with prophylaxis is a key consideration in any immunosuppressed host. The inability to objectively measure the "net state of immunosuppression" means providing universal guidelines for screening and prophylaxis that apply to all hosts is not possible. This lack of a "global guideline" has necessitated numerous international and regional guidelines based on patient group.[21–33]

Pre-immunosuppression Assessment

Pre-immunosuppression assessment including management of active and latent infection can prevent considerable morbidity and mortality. Pre-immunosuppression screening varies by patient, exposures, and treatment group, but should at a minimum include HIV, hepatitis B virus, hepatitis C virus, *Treponema pallidum* (syphilis), *M. tuberculosis*, and *Strongyloides stercoralis*. Additional screening may be required based on epidemiologic, patient, and treatment factors (e.g., *Coccidioides* sp., malaria, *Toxoplasma gondii*, *Trypanosoma cruzi*). Ideally, any active infections are treated prior to initiation of immunosuppression.

Pre-immunosuppression assessment for *M. tuberculosis* should be undertaken in all patients, given its high global prevalence, capacity for prolonged latency, and potential for high morbidity and mortality with reactivation. In the those without active tuberculosis, careful questioning on potential exposure, previous testing results, and previous treatment should be undertaken in order to determine level of risk. In addition to history, screening for latent tuberculosis typically involves a test of T-cell memory to *M. tuberculosis* exposure with either tuberculin skin test (TST) or interferon-γ (IFN-γ) release assay.[34] Both tests can be falsely negative, particularly in those already on immunosuppression or with active tuberculosis. IFN-γ release blood assays are more sensitive than TST, while maintaining high specificity for *M. tuberculosis* exposure.[35] In high-risk individuals with a negative IFN-γ release assay, chest CT is another tool to examine for previous *M. tuberculosis* exposure. Of note, previous vaccination with bacillus Calmette-Guérin may lead to false-positive TST (but not IFN-γ release assay); clinicians should exercise great caution before discounting a positive TST in vaccinated individuals, as vaccination does not provide universal protection from *M. tuberculosis* infection and true latent infection may still be present. As both TST and IFN-γ release assays are imperfect, results must be interpreted in context of the patient's epidemiologic risk. Where uncertainty exists, expert consultation is recommended, even if TST and/or IFN-γ release assay is negative. Treatment guidelines for latent tuberculosis are widely available;[34] of particular importance is the need to exclude active tuberculosis before treating for latent tuberculosis (Chapter 130). *Strongyloides* screening should be undertaken in those with epidemiologic risk or unexplained eosinophilia. *Strongyloides stercoralis* is a problematic pathogen in immunocompromised hosts and is ideally treated pre-emptively prior to any immunosuppression, given the risk of hyperinfection syndrome and associated high mortality.

Prevention of infection in immunocompromised hosts also includes patient education on measures to minimize epidemiologic exposure to potential pathogens and comprehensive vaccination.[36] Ideally, vaccines are given prior to onset of any immunosuppression to maximize likelihood of lasting immunogenic response. Allogeneic HSCT recipients should also undergo a process of re-vaccination following engraftment, usually beginning at 3 to 6 months post-HSCT.[1,37] Yearly influenza vaccine and up-to-date *B. pertussis* and *S. pneumoniae* vaccines are important for preventing pulmonary complications of immunosuppression.[1] Of note, live vaccines should not be given in the setting of immunosuppression.

Primary Prophylaxis for Pulmonary Infections

In general, commonly targeted organisms for prophylactic antimicrobials include herpes simplex virus, varicella zoster virus, CMV, hepatitis B virus, *Pneumocystis jirovecii*, and *Toxoplasma gondii*. The following focuses on prevention of pulmonary infection in immunocompromised hosts and does not consider all the prophylaxis that may be required for nonpulmonary infections.

Viruses

Prophylaxis of viral lung infection is usually reserved for those with hematologic malignancies as well as SOT and HSCT recipients, and is targeted towards herpes viruses, particularly reactivation of herpes simplex virus, varicella zoster virus, and, in those at risk, CMV.[21,27,28,32,33] Oseltamivir prophylaxis might be given to an individual at high risk for severe influenza after a significant influenza contact.

Bacteria

Antibacterial prophylaxis for lung infection is rarely used as antimicrobial resistance readily emerges, which can impair future treatment for bacterial infection. Lung transplant recipients occasionally receive prolonged antibacterial prophylaxis following perioperative prophylaxis based on specific transplant center and patient factors, including prior colonization and risk of bronchial anastomosis infection. Prophylaxis for *Mycobacterium avium* complex is employed occasionally for people with HIV and CD4+ T-cell count below 50 cells/μL.[23]

Fungi

Antifungal prevention is predominantly employed to prevent *Pneumocystis*. Unfortunately, *Pneumocystis* prophylaxis can be inadvertently omitted by inexperienced clinicians when immunosuppression is used infrequently, despite clear guidelines.[38] Indications for *Pneumocystis* prophylaxis are broad, and clinicians should consider the net state of immunosuppression when being interpreted. Trimethoprim/sulfamethoxazole is a unique prophylactic agent; it is the most effective agent for preventing *Pneumocystis* but also has efficacy in preventing *Toxoplasma gondii* reactivation, some *Nocardia* sp. infections, *Listeria monocytogenes*, and many other Gram-positive and Gram-negative bacteria (although susceptibility patterns many change over time, making prevention of Gram-positive and Gram-negative infections less effective). Second-line options for *Pneumocystis* prophylaxis include atovaquone, dapsone, and pentamidine.[38]

Anti-mold prophylaxis is used following HSCT, lung transplant, and liver transplant in some centers depending on local epidemiology and patient-specific characteristics.[25] Potential benefits of anti-mold prophylaxis must be determined based on local epidemiology and balanced against cost and risk of driving antifungal resistance. Prophylaxis for reactivation of *Coccidioides* sp. is employed in those with previous exposure following SOT.[26]

Parasites

Antiparasitic prophylaxis for pulmonary infection is rarely required except for *Toxoplasma gondii* in HSCT recipients and patients with HIV and CD4+ less than 100 cells/μL.[23] A course of ivermectin may be given for those at risk for strongyloidiasis.

EVALUATION OF AN IMMUNOCOMPROMISED INDIVIDUAL WITH POSSIBLE PULMONARY INFECTION

Bedside evaluation of the immunocompromised patient includes taking a thorough history, performing a detailed physical examination, and undertaking a targeted laboratory assessment.

History

There are several features of the clinical history of particular importance to the immunocompromised host. As noted above, establishing the net state of immunosuppression is vital in evaluation of an immunocompromised host to determine their likelihood of

TABLE 123-3 Geographic Considerations for Pulmonary Infections in Immunocompromised Hosts

Disease	Organisms	Most Common Regions
Melioidosis	*Burkholderia pseudomallei*	Southeast Asia, northern Australia
Anthrax	*Bacillus anthracis*	South America, central and southwestern Asia
Histoplasmosis	*Histoplasma capsulatum*	Eastern United States, sub-Saharan Africa
Coccidioidomycosis (valley fever)	*Coccidioides immitis*	Southwestern United States, Central and South America
Cryptococcosis	*Cryptococcus gattii*	Australia, U.S. Pacific Northwest, Canada (Vancouver Island, British Columbia), Papua New Guinea
Paracoccidioidomycosis	*Paracoccidioides brasiliensis*	Central and South America
Talaromycosis (previously called penicilliosis)	*Talaromyces marneffei*	Southeast Asia, northeastern India, southern China
Blastomycosis	*Blastomyces dermatitidis*	Eastern United States and Canada, Africa
Strongyloidiasis	*Strongyloides stercoralis*	Southeast Asia, Africa, Western Pacific and Northern Australia

particular infections. This consideration is frequently overlooked, and treating clinicians as well as the patient may not recognize its importance. A clear understanding of the patient's medical history, timeline of immunomodulatory medications received, and previous infections is vital.

Establishing the nature and time course of epidemiologic exposures is of the utmost importance in immunocompromised hosts, where even very remote exposure to an infectious agent can be relevant (e.g., childhood exposure to tuberculosis, or remote exposure during the Vietnam war to *Strongyloides*).[39] The immunocompromised state predisposes to infections that can manifest in immunocompromised hosts that may otherwise have been quiescent, or that may manifest more severely or in an atypical manner. As with all hosts, consideration of prior travel history is important for understanding potential exposures in endemic regions of particular infections (Table 123-3). Some of these exposures are environmental, such as endemic fungi[40] (Fig. 123-3), *Burkholderia pseudomallei*, and *Legionella*; some are zoonotic, such as *Coxiella burnetii* or Middle East Respiratory Syndrome; and some are human-related, such as *Mycobacterium tuberculosis*, influenza, and SARS-CoV-2. In solid organ transplant recipients, consideration of epidemiologic exposures of the organ donor may be required, particularly with regard to the risk of transmission of tuberculosis, coccidioidomycosis, and strongyloidiasis.[41–43]

Animal exposures pose greater health risks to immunocompromised hosts than immunocompetent hosts. Examples of potential pulmonary pathogens due to animal exposure are shown in Table 123-4.

Several diseases warrant specific note due to their epidemiology and potential for prolonged latency from exposure that can reactivate in the setting of commencing immunosuppressive medication or developing immunocompromised state, including

tuberculosis,[44–47] strongyloidiasis,[48] coccidioidomycosis,[49,50] toxoplasmosis,[51,52] melioidosis,[53] paracoccidioidomycosis,[54] and penicilliosis (*Talaromyces marnefei*).[55,56] Most recent exposures should be considered for all hosts, especially for immunocompromised patients, where apparently trivial exposure can lead to infection and cause disease. Frequently, potential exposure to such pathogens can be determined from a thorough epidemiologic history with common risk factors, as shown in Table 123-5.

Understanding the effects of immunosuppressive medication is essential, including the potential duration of their effect on the immune system.[57] Some drugs have prolonged half-lives with intermittent infusions separated by many months. Clinicians should be mindful in considering the prolonged effects of these medications on the host immune system. Examples include many monoclonal antibodies (for example, anti-CD20, anti–TNF-α, anti–IL-6) and antithymocyte globulin. Additionally, the immune effects of many medications may linger for weeks beyond medication cessation due to long drug half-life—for example, leflunomide and methotrexate.

Many immunocompromised patients are prescribed antimicrobial prophylactic agents including agents targeted to *Pneumocystis jirovecii* (trimethoprim-sulfamethoxazole, atovaquone, dapsone, pentamidine), herpes simplex and herpes zoster (acyclovir, famciclovir, valacyclovir, valganciclovir), cytomegalovirus (valganciclovir, letermovir), fungi (fluconazole, voriconazole, posaconazole, itraconazole, isavuconazole, amphotericin [inhaled/systemic]), and other bacteria (ciprofloxacin, amoxycillin, doxycycline). Importantly, the efficacy of each of these agents toward their target varies and relies on adequate dosing, absorption, and patient adherence. Thus, prophylaxis may not always exclude an organism being implicated in a pulmonary presentation. For example, atovaquone is frequently substituted for trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* prophylaxis; however, atovaquone is less effective than trimethoprim-sulfamethoxazole and may lead to breakthroughs.[58] Similarly, prophylaxis may change the organisms encountered. For instance, antifungal prophylaxis with voriconazole among high-risk HSCT recipients may reduce aspergillosis but increase the risk of mucormycosis.[59]

Consideration should be given to vaccination history. The efficacy of vaccines in immunocompromised hosts is often reduced.

TABLE 123-5 Risk Factors for Exposures to Organisms with Potential to Reactivate Following Immunosuppression

Disease	Organism	Risk Factors for Exposure
Tuberculosis	*Mycobacterium tuberculosis*	Relative or close contact with tuberculosis Health care workers Residency/prolonged travel in an endemic country Prison workers/previous incarceration Homelessness
Coccidiomycosis	*Coccidioides* sp.	Residency or travel to Southwestern United States, Mexico, Central America (Fig. 123-3)
Strongyloidiasis	*Strongyloides stercoralis*	Residency/prolonged travel in an endemic region (includes much of Asia, Africa, South America, Pacific Island, Northern Australia), including military service
Toxoplasmosis	*Toxoplasma gondii*	Feline/animal exposure, consumption of contaminated foods or undercooked infected
Melioidosis	*Burkholderia pseudomallei*	Residency/prolonged travel in endemic region (Southeast Asia especially Thailand, Vietnam, Cambodia, Myanmar, Philippines, Malaysia, Indonesia, Papua New Guinea; Northern Australia)
Paracoccidioides	*Paracoccidioides* sp.	Residency in Central and South America
Talaromycosis (previously called penicilliosis)	*Talaromyces marneffei*	Residency/prolonged travel in Southeast Asia

Hence, the presence of a previous vaccine does not exclude the possibility of disease in many vaccine-preventable diseases and may alter the clinical presentation.

As with all hosts, timeline and constellation of symptoms is important to understand. When taking a history from an immunocompromised host, several aspects are worth noting:

- Fever may not be recognized or may not be present.
- Purulence may be less than expected—for example, purulent sputum may be minimal in bacterial pneumonia.
- Clinical course may be different or vague compared with that which typically occurs in immunocompetent hosts.
- COVID-19 may have shorter prodrome, with a more rapid onset of hyperinflammatory phase. Alternatively, some patients may have a prolonged prodrome and the hyperinflammatory phase may not occur until much later than expected.
- Some opportunistic infections have "typical" presentations, such as *Pneumocystis* pneumonia in patients with HIV and low CD4+ T-cell count (Chapter 134).

Physical Examination

Systematic and thorough bedside examination has the potential to yield important information. Clinicians should be mindful that clinical signs may be altered in the setting of some immunocompromised states, including diminished or absent fever and reduced signs of inflammation, with absent or minimal purulence or erythema than would otherwise be anticipated (Fig. 123-4). In solid organ transplant recipients, transplanted organs are denervated and may not exhibit typical signs of infection or inflammation.

The importance of examination beyond the respiratory system is vital given the potential for many pulmonary pathogens to have disseminated or metastatic foci. For example, the presence of a skin rash or nodule may be key to the diagnosis of disseminated *Fusarium*, *Nocardia*, or *Cryptococcus*. Similarly, focal neurologic findings may give a clue to *Nocardia* or *Aspergillus* brain infection. All recent and former surgical sites should be examined carefully, even if remote, as such sites may provide a site of least resistance (*locus minoris resistentiae*) for entry and/or establishment of an infectious process. Joints should be examined carefully given the potential for pulmonary pathogens to involve bones and joints—for example, *Streptococcus pneumoniae* and *Mycobacterium tuberculosis*. A detailed physical examination may also help elicit processes that mimic pulmonary infection.

Diagnostics

A key principle of the approach to an immunocompromised host is the importance of specific and accurate diagnosis. The breadth of potential infectious agents that may contribute to pulmonary disease are too broad to accurately cover empirically in many circumstances, necessitating rapid and definitive measures to obtain

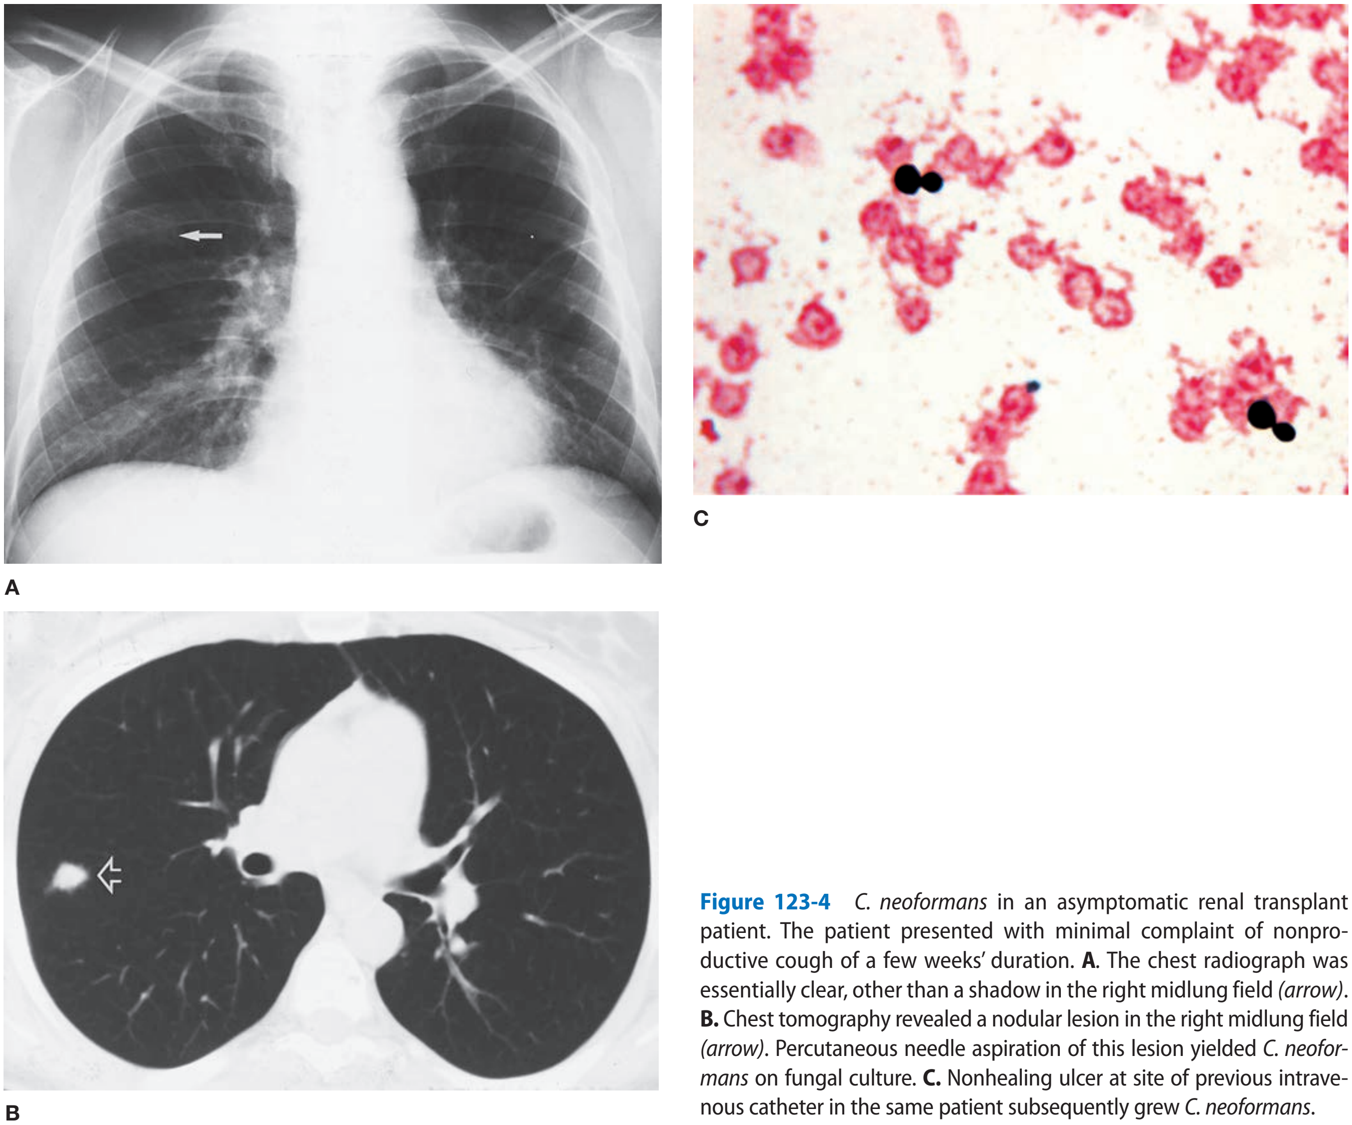

Figure 123-4 *C. neoformans* in an asymptomatic renal transplant patient. The patient presented with minimal complaint of nonproductive cough of a few weeks' duration. **A.** The chest radiograph was essentially clear, other than a shadow in the right midlung field *(arrow)*. **B.** Chest tomography revealed a nodular lesion in the right midlung field *(arrow)*. Percutaneous needle aspiration of this lesion yielded *C. neoformans* on fungal culture. **C.** Nonhealing ulcer at site of previous intravenous catheter in the same patient subsequently grew *C. neoformans*.

TABLE 123-6 Causes of Neutropenia

- Iatrogenic
    - Cancer chemotherapy
    - Drug toxicities (TMP–SMX, chloramphenicol, ganciclovir, AZT, allopurinol)
- Infection
    - Viral (cytomegalovirus, HIV, Epstein–Barr virus, hepatitis B)
    - Parasitic *(Leishmania)*
    - Bacteria *(Clostridium)*
    - Acute neutropenia of sepsis/endotoxemia (Gram-negative sepsis)
    - Bone marrow failure of neonatal sepsis
- Immune
    - Drug-induced autoimmunity (haptenic: penicillins, sulfa drugs)
    - Aplastic anemia (includes idiosyncratic reactions: phenothiazines, chloramphenicol)
    - Alloimmune neonatal neutropenia (maternal–fetal incompatibility)
    - Congenital autoimmune neutropenia
    - Primary autoimmune (systemic lupus erythematosus, Felty syndrome, rheumatoid arthritis)
    - Transfusion-induced
    - Antineutrophil antibody–mediated
    - Cyclic neutropenia (CD57 lymphocyte expansion)
- Hereditary
    - Infantile genetic agranulocytosis
    - Familial neutropenia
    - Cyclic neutropenia (autosomal dominant)
    - Advanced age

diagnostic samples in order to promptly make a diagnosis and guide appropriate therapy.

Basic Investigations

In general, initial diagnostic testing is similar to that of an immunocompetent host. Initial testing includes chest x-ray and basic laboratory markers including complete blood examination and biochemistry. Lymphopenia may be a function of immunosuppressive agents rather than viral infection. Nonetheless, considering relative lymphopenia compared with previous results can be useful. In patients on more than 5 mg prednisone or equivalent, eosinophil count should almost always be very close to 0. If not, pathology causing elevated eosinophil lineage should be considered, most commonly drug reactions or parasitic infection. In organ transplant recipients, allograft rejection should always be considered in the differential of elevated eosinophil count.[60] Neutropenia is an important consideration given its association with bacterial and fungal infections, especially if prolonged. Potential causes of neutropenia are outlined in Table 123-6.

Radiology Radiology is an essential component of diagnostic workup for immunocompromised hosts with suspected pulmonary infection. While often nonspecific, pulmonary imaging can aid considerably in the creation of a differential diagnosis. The chest x-ray may be falsely reassuring in immunocompromised hosts. Thus, a low threshold is required for cross-sectional imaging with CT (ideally high resolution if indicated, and with intravenous radiocontrast when needed). High-quality cross-sectional imaging may provide important clues to the implicated organism and more accurately target diagnostics. Common differential diagnoses based on radiographic appearance are shown in Table 123-7.

Similar to inflammatory biomarkers markers (below), radiology may be less dramatic than anticipated for severity of infection owing to a lack of inflammatory response. Further, following institution of appropriate antimicrobial therapy, reduction of immunosuppression, or recovery of neutrophil count there may be an apparent radiographic worsening that may be paradoxical to clinical response (see “Immune Reconstitution Syndrome: a Diagnosis of Exclusion,” below).

While radiographic findings may assist in creation of a differential diagnosis list, no individual radiographic finding is sufficient to confirm a diagnosis. Each radiographic appearance (Table 123-7) is associated with a broad list of differential diagnoses. An example is a “halo sign” (Fig. 123-5), which is commonly associated with invasive pulmonary aspergillosis. However, numerous infectious and noninfectious etiologies can produce this sign, leaving the radiographic feature as suggestive but not diagnostic.[61–69] The presence of a “reverse halo sign” is commonly associated with mucormycosis but also is not diagnostic.[65,70,71] Both signs provide clues and may guide empiric therapy, but they do not obviate the additional necessary investigations to arrive at a specific diagnosis.

Ground-glass opacities are a frequent radiographic finding in immunocompromised individuals with pulmonary symptoms (Figs. 123-6 and 123-7). Once again, the differential diagnosis of

TABLE 123-7 Infectious and Non-infectious Differentials for CT Chest Findings

Mediastinal lymphadenopathy	Bacterial pneumonia Viral pneumonia Fungal pneumonia *M. tuberculosis* Nontuberculous *Mycobacteria* HIV infection	Malignancy Sarcoidosis Reactive to pulmonary process

this finding is broad, including infectious etiologies like viral pneumonia and pneumocystis, but also noninfectious etiologies like lung transplant rejection, pulmonary edema, and drug hypersensitivity.[9]

Thus, while radiology is a helpful aid, it is rarely able to provide specific diagnosis of a causative pathogen in isolation. This highlights the importance of obtaining specific microbiologic diagnoses in patients with potential pulmonary infection as much as possible.

When considering the immunocompromised host with pulmonary infection, care should be taken to consider the need to

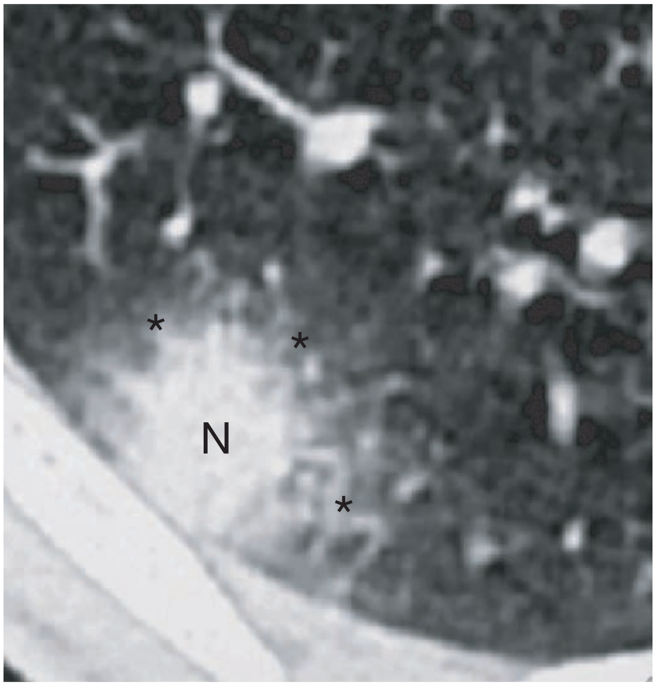

Figure 123-5 "Halo" sign in angioinvasive aspergillosis. CT scan of patient with fever and prolonged neutropenia during therapy for hematopoietic malignancy demonstrates a macronodule *(N)* surrounded by a halo of ground-glass opacity *(*)*.

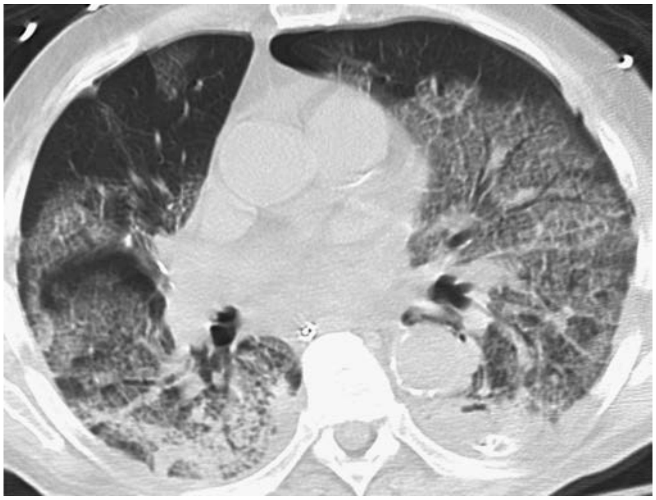

Figure 123-6 Diffuse ground-glass opacity of *P. jirovecii* pneumonia in advanced HIV at the time of initial presentation predominantly involved the subpleural lung and spared the central lung.

image other areas—in particular, areas such as the brain in pulmonary cryptococcosis, aspergillosis, nocardiosis, or toxoplasmosis (Fig. 123-8).

Inflammatory Biomarkers The measurement of inflammatory biomarkers, such as C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and procalcitonin should be undertaken only with knowledge of their limitations in immunocompromised hosts, particularly those on immunosuppressive medications. CRP and ESR are nonspecific markers of inflammation and can be falsely low in immunocompromised patients with severe bacterial infection due to a muted inflammatory response. Furthermore, immunocompromised hosts frequently have reasons for noninfectious elevations of CRP/ESR, such as underlying malignancy, an autoimmune disorder, or organ transplant rejection.[72–76]

Procalcitonin is a novel biomarker studied in immunocompetent hosts and has an evolving role that may allow discrimination between bacterial and viral infection or noninfection. In immunocompromised hosts, especially those on immunosuppressive medications, the role of procalcitonin remains understudied. While procalcitonin may be more useful than CRP or ESR in predicting bacterial infection, studies have not demonstrated superiority to bedside clinical judgement.[77–83] The test may have some value in distinguishing bacterial infection from organ transplant rejection,[80,81] but procalcitonin has also been shown to increase readily following induction immunosuppression with antithymocyte globulin in solid organ and hematopoietic stem cell transplant recipients.[82]

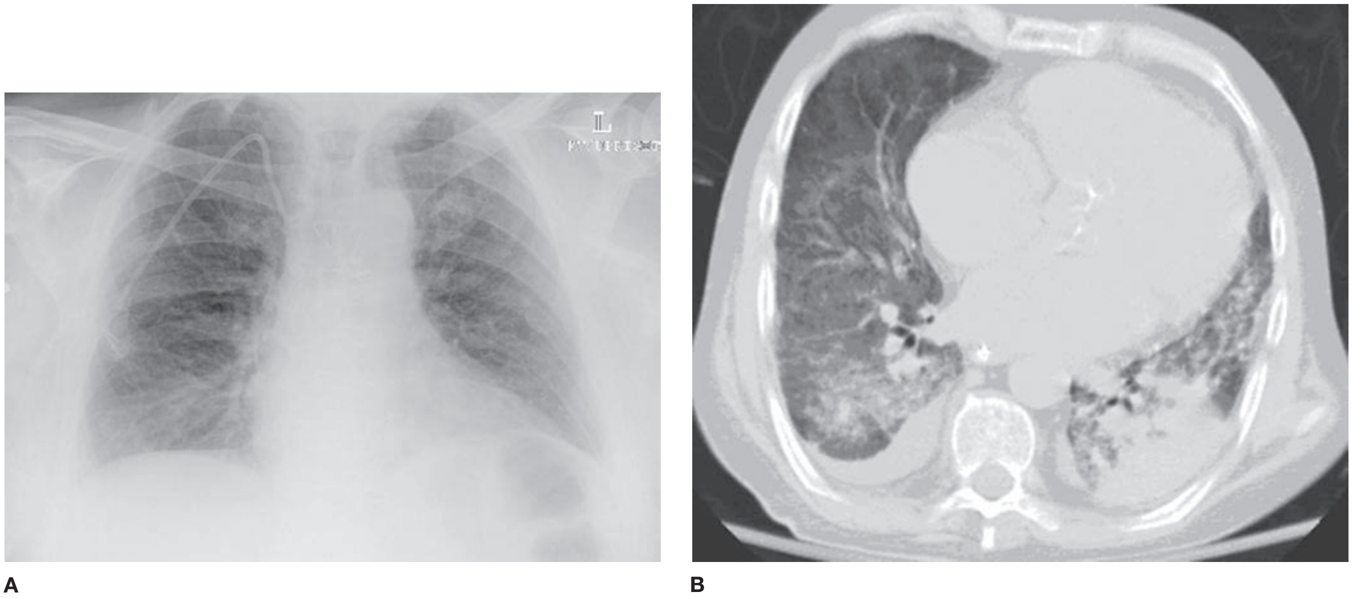

Figure 123-7 Diffuse process on plain radiograph (**A**) of *Pneumocystis* pneumonia 8 weeks following hematopoietic stem cell transplantation for T-cell lymphoma. CT scan (**B**) revealed pattern most consistent with aspiration pneumonia. Bronchoalveolar lavage revealed *Pneumocystis* and antimicrobial-resistant *K. pneumoniae*. Treatment of both processes resulted in resolution of infection.

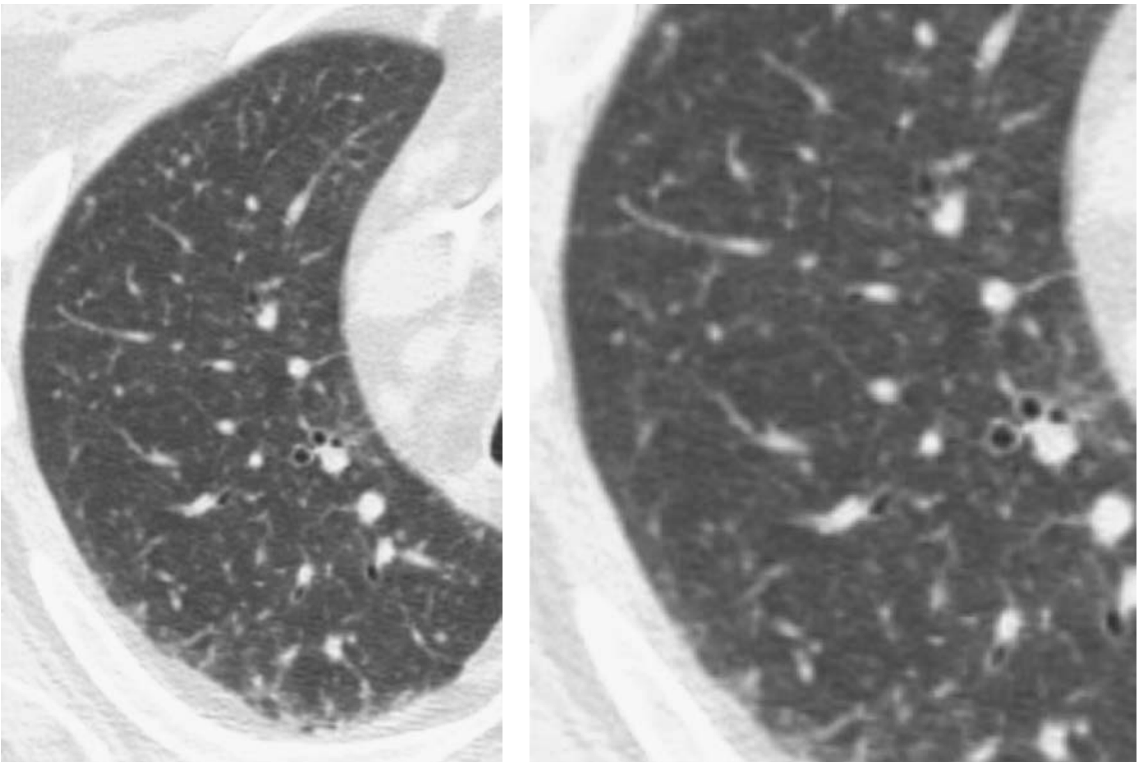

Figure 123-8 Miliary cryptococcal pneumonia in a 62-year-old man undergoing intensive chemotherapy for pancreatic cancer. *C. neoformans* was isolated from bronchoalveolar lavage specimens and cerebrospinal fluid (CSF). Cryptococcal antigen was positive in serum and CSF at titers greater than 1:1024. CT scan demonstrates diffuse 1- to 3-mm micronodules in both lung fields, often difficult to distinguish from small blood vessels on end. This requires review of serial CT cuts to distinguish nodules from tubular vessel structures.

Overall, elevated CRP, ESR, or procalcitonin should raise consideration of a potential bacterial or fungal infection in immunocompromised hosts, but a low value does not reliably exclude the possibility of infection.

Non-culture-based Microbial Diagnostics Non-culture-based microbial diagnostics include molecular tests, serologic tests, specific antigen tests, nonspecific fungal markers, and metagenomic sequencing.

Molecular Tests Viral polymerase chain reaction (PCR) from upper respiratory tract or lower respiratory tract specimens are useful tests for many common respiratory illnesses, including those in immunocompromised hosts (Chapter 122). Viral infections such as respiratory syncytial virus, influenza, human metapneumovirus, and parainfluenza can cause severe disease in many immunocompromised hosts, particularly solid organ transplant recipients (especially lung transplant recipients) and following HSCT.[84,85] Similarly, the occurrence of a viral infection may increase the risk of developing chronic lung allograft dysfunction or bronchiolitis obliterans syndrome in lung transplant recipients and chronic lung dysfunction following HSCT.[86–88] Depending on local epidemiology, PCR testing for SARS-CoV-2 also should be considered. Common multiplex panels include respiratory syncytial virus, human metapneumovirus, parainfluenza, enterovirus, rhinovirus, influenza, and adenovirus, and increasingly, SARS-CoV-2.[89,90] Adenovirus is of particular importance in HSCT and SOT recipients, where it has the ability to cause disseminated disease with multiorgan manifestations (Fig. 123-9). PCR testing may also be undertaken for atypical pathogens, such as *Mycoplasma pneumoniae* and *Bordetella pertussis*, which can cause severe disease in immunocompromised patients.[89,91,92] PCR testing sensitivity and specificity vary by assay and organism; thus, the clinician should have knowledge of particular test characteristics of the local laboratory. The site of sampling can also alter test sensitivity. Typically, in patients with pulmonary manifestations of any of these infections, the most sensitive samples are those obtained from the lower respiratory tract, such as sputum or BAL.[93,94]

Peripheral blood samples for PCR can be useful for diagnosis of a number of pulmonary-based infections, including CMV, adenovirus, and, rarely, primary EBV infection. CMV pneumonitis is a rare manifestation of CMV disease occurring primarily in HSCT and lung transplant recipients. Rarely, CMV pneumonitis can occur in lung transplant recipients with negative peripheral blood PCR, although this phenomenon is much less common in the era of high-sensitivity CMV assays. Where suspicion of CMV pneumonitis persists despite a negative peripheral blood PCR, pulmonary tissue for PCR or via immunohistochemical staining is the preferred method of diagnosis, as BAL CMV PCR may reflect asymptomatic viral shedding.[21]

Pneumocystis jirovecii PCR is increasing in availability and can be performed on induced sputa and BAL specimens. A positive *Pneumocystis* PCR must be interpreted in conjunction with clinical syndrome and other markers, as it is unable to distinguish airway colonization from true infection. In a vulnerable host (see "The Net State of Immunosuppression," above) with a compatible clinical syndrome and radiologic findings, elevated LDH and 1,3 Beta-d-glucan are useful adjunctive markers that support a diagnosis of *Pneumocystis* infection over colonization when *Pneumocystis* PCR is positive but direct visualization methods are negative.[22,95–97] The use of quantitative PCR may further enhance our ability to differentiate colonization from infection.[98,99]

Aspergillus PCR (Chapter 132) has been studied in blood/serum and BAL samples; BAL testing has a higher overall sensitivity.[100–102] PCR on BAL specimens lacks the ability to differentiate between colonization and infection, especially in lung transplant recipients. Furthermore, while some assays can detect some genes responsible for azole resistance, the lack of phenotypic antifungal susceptibility data means this test currently serves primarily as an adjunct to culture data.[89]

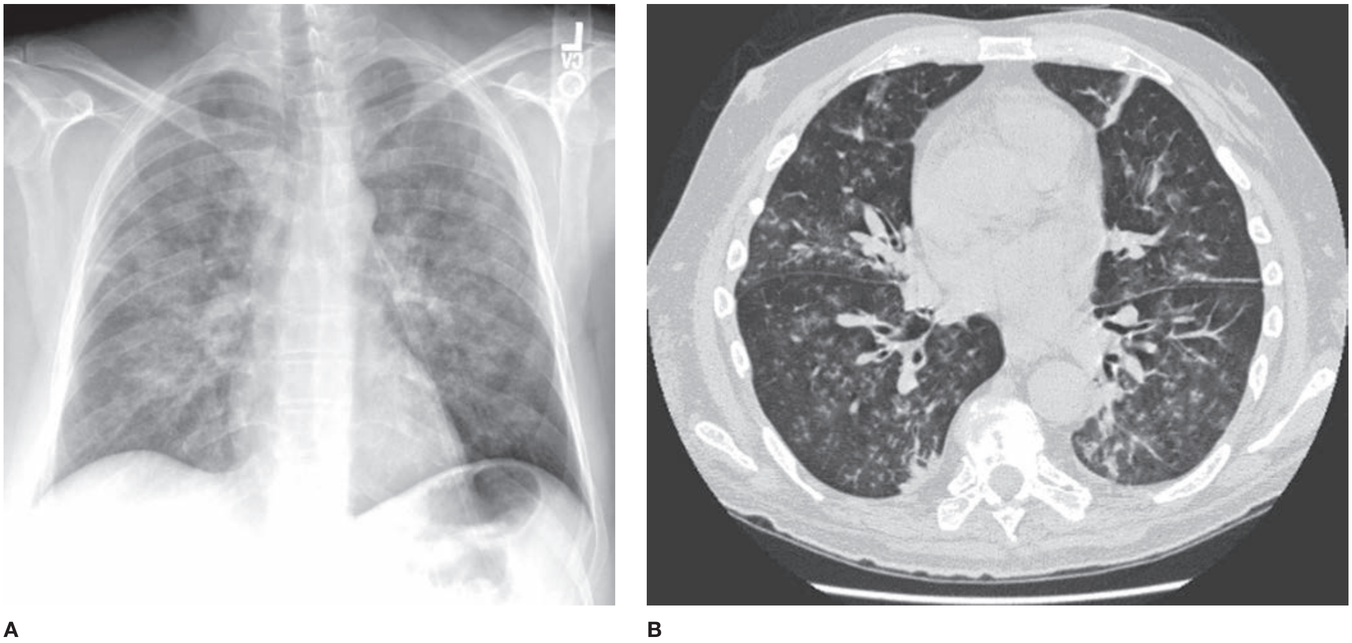

Figure 123-9 Adenovirus pneumonia during week after marrow engraftment following allogeneic hematopoietic stem cell transplantation for acute myelogenous leukemia. Routine chest radiograph (**A**) reveals diffuse pneumonia while CT scan (**B**) demonstrates bronchiolitis. The patient failed to respond to cidofovir therapy but cleared infection after infusion of autologous stem cells.

Serology Serologic testing is rarely useful in the acute phase of a respiratory illness, especially in immunocompromised hosts who may have impaired antibody responses to infection. Serologic testing may be useful for a select few set of infections with prolonged prodrome. Potential serologic tests that may be of use in diagnosis of chronic infection include tests for *Coccidioides*,[103] *Paracoccidioides*,[104] *Histoplasma capsulatum*, *Toxoplasma gondii*, and *Burkholderia pseudomallei.* Sensitivity of serologic testing is particularly poor in immunocompromised hosts and may only establish a history of possible exposure and the potential for the organism to reactivate. Thus, the utility of serologic testing is limited in diagnosing acute infection. In the setting of HSCT and SOT, pretransplant serology for CMV of donor and recipient can help define the risk of CMV disease following transplantation, as shown in Table 123-8.[21,32] EBV-seronegative SOT recipients are at risk of primary EBV and post-transplant lymphoproliferative disorder, especially if the donor is EBV IgG-positive.[105] EBV-related PTLD can occur following HSCT, particularly with EBV mismatch between donor and recipient.[106]

Specific Antigen Testing Serum cryptococcal antigen (Chapter 133) has high specificity and sensitivity in patients with disseminated *Cryptococcus*, particularly in patients with HIV, but may be negative in patients with isolated pulmonary disease.[107–109] Care should be taken for patients with potential neurologic disease, where lumbar puncture and CSF cryptococcal antigen are still required where clinical suspicion remains, even if peripheral blood cryptococcal antigen is negative. This noninvasive test rarely represents a false positive (although this may occur with disseminated infection due to *Trichosporon asahii*, or some rare bacterial species). The timeline for decay of this marker is long and remains positive following successful treatment completion of cryptococcosis for months to years.[110,111] Thus, it has limited role in monitoring treatment response. Referral of the clinical specimen to an experienced laboratory is required to in order to minimize risk of a false negative from inappropriate handling or failure to assess for a prozone effect.[112,113] In HIV-infected individuals, some guidelines include screening for *Cryptococcus* with serum cryptococcal antigen when the CD4+ count is less than 100 cells/µL.[114] However, screening is not recommended in other populations unless disease is suspected. This is a useful test in a number of immunocompromised hosts with suspected cryptococcosis.

As in immunocompetent hosts, urinary and serum antigen testing should be considered for coccidiomycosis, histoplasmosis, and blastomycosis in those with epidemiologic risks and a compatible clinical syndrome. There is cross-reactivity among the endemic fungi assays, and limited sensitivity means a negative test does *not* exclude infection with either of these organisms.[26,115]

Urinary antigen tests are often limited by sensitivity. The most useful test is a urinary *Legionella* antigen, although this does not test for all serotypes relevant to a given geographic region, further reducing sensitivity.[116] The utility of a *Streptococcus pneumoniae* urinary antigen test is questionable among immunocompetent adults, in whom standard antibiotic regimes may not be altered by a positive or negative result. Similarly, the role of this test is also not clear in immunocompromised hosts.

Nonspecific Fungal Markers There are several nonspecific markers that can be utilized in immunocompromised patients with potential fungal infection.

TABLE 123-8 Risk of CMV in SOT and HSCT Recipients by Serostatus of Donor and Recipient

CMV Status	Donor IgG Pretransplant	Recipient IgG Pretransplant	Risk Category
SOT	+	–	High risk
	+/–	+	Moderate risk
	–	–	Low risk
HSCT	–	+	High risk
	+	+/–	Moderate risk
	–	–	Low risk

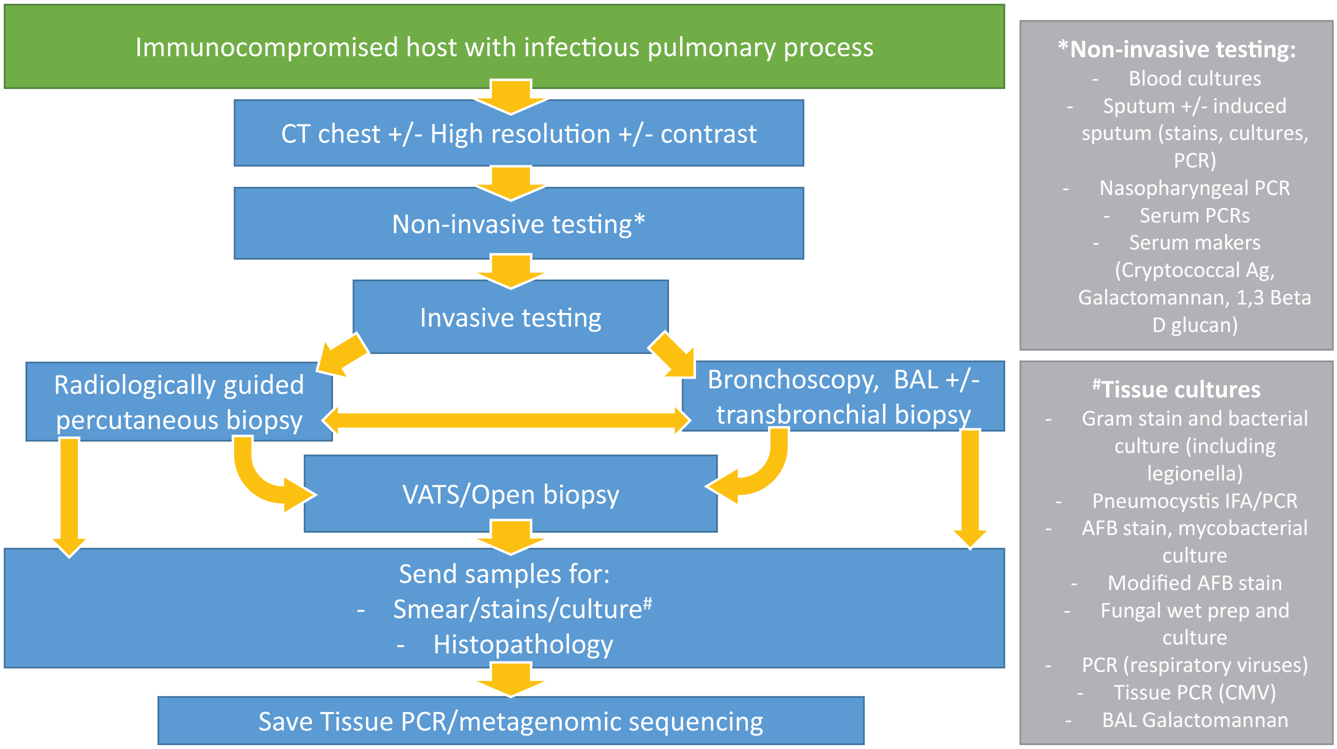
1,3 Beta-D-glucan is a component of cell walls of *Candida* species, *Aspergillus* species, and *Pneumocystis jirovecii*. Several assays measuring 1,3 Beta-D-glucan have been developed. Test results can be elevated with localized or systemic infections due to any of these organisms, and testing can be performed in serum and BAL samples. However, detection of 1,3 Beta-D-glucan has poor specificity, limiting its ability to accurately guide diagnostic and therapeutic decisions.[117–122] False positives are also problematic.[123–127] The role of 1,3 Beta-D-glucan in distinguishing *Pneumocystis jirovecii* colonization from infection is emerging; however, its ability to incrementally improve diagnostic accuracy beyond clinical acumen is untested.[96,128] Furthermore, it is not typically elevated due to infection with other fungi, such as mucormycosis and cryptococcosis (which do not contain 1,3 Beta-D-glucan in their cell walls). Hence, this test does not perform as a "pan-fungal marker,"[120,129] and the diagnostic role of 1,3 Beta-D-glucan remains unclear.

Galactomannan (*Aspergillus* antigen) is another fungal marker that may be measured in peripheral blood or BAL specimens and is specific for *Aspergillus* species (Chapter 132). Utility of peripheral blood galactomannan is predominantly limited to patients with hematologic malignancy or HSCT recipients, particularly when they are neutropenic and are not taking mold-active antifungal prophylaxis.[130,131] In other immunocompromised patients, such as solid organ transplant recipients and those with chronic granulomatous disease, sensitivity of blood galactomannan for invasive aspergillosis is poor.[132–135] Sensitivity may also be lower with isolated pulmonary aspergillosis without angioinvasion.[136] Some institutions have adopted a strategy to serially monitor blood galactomannan in HSCT recipients to "screen" for invasive *Aspergillus* infection, as serum galactomannan positivity may precede clinical diagnosis of invasive *Aspergillus* infection[137,138] in those not prescribed mold-active antifungal prophylaxis.[139] Galactomannan on BAL fluid has improved test characteristics compared with peripheral blood galactomannan and is a suitable test for any immunocompromised patient with suspected invasive pulmonary aspergillosis. Sensitivity remains highest in those with hematologic malignancy and following HSCT and is reasonably high in other immunocompromised patient groups with suspected invasive pulmonary aspergillosis, particularly solid organ transplant recipients.[119,140,141] BAL galactomannan maintains higher performance characteristics, even in those receiving mold-active antifungal prophylaxis.[142] In lung transplant recipients, BAL galactomannan is not able to distinguish between airway colonization and invasive aspergillosis.[143,144] False positives can occur, in addition to cross-reactivity with other infections,[145–150] underlining the importance of continuing to pursue specific diagnosis with sampling and culture in patients with positive galactomannan. In all patient groups, BAL galactomannan sensitivity is not high enough to exclude pulmonary aspergillosis when used in isolation.

Metagenomic Sequencing Metagenomic sequencing is an emerging technology with an evolving role in clinical practice.[89] Currently, clinical use is generally limited to circumstances where standard microbiologic, molecular, and pathologic methods have failed to yield a causative organism.

Data are emerging from studies addressing earlier institution of this technology.[151] Sequencing can be performed on blood, tissue, and respiratory specimens, although sensitivity and specific of such samples vary widely.[152–155] In the future, this technology may prove a powerful tool in specific diagnosis among immunocompromised patients in whom standard diagnostic methods are often negative.

Culture-based Diagnostics: Sampling and Microbiology Those with respiratory presentations will generally have culture-based diagnostics targeted toward samples obtained from the respiratory tract. The suggested flow of sampling is shown in Fig. 123-10 and covered in Chapter 31. Where possible, a sufficient sample volume should be obtained to undertake all necessary tests, ideally those listed



Immunocompromised host with infectious pulmonary process
CT chest +/- High resolution +/- contrast
Non-invasive testing*
Invasive testing
Radiologically guided percutaneous biopsy
Bronchoscopy, BAL +/- transbronchial biopsy
VATS/Open biopsy
Send samples for:
- Smear/stains/culture#
- Histopathology
Save Tissue PCR/metagenomic sequencing
*Non-invasive testing:
- Blood cultures
- Sputum +/- induced sputum (stains, cultures, PCR)
- Nasopharyngeal PCR
- Serum PCRs
- Serum makers (Cryptococcal Ag, Galactomannan, 1,3 Beta D glucan)
#Tissue cultures
- Gram stain and bacterial culture (including legionella)
- Pneumocystis IFA/PCR
- AFB stain, mycobacterial culture
- Modified AFB stain
- Fungal wet prep and culture
- PCR (respiratory viruses)
- Tissue PCR (CMV)
- BAL Galactomannan

Figure 123-10 Suggested diagnostic workup of pulmonary infection in immunocompromised host. Choice of invasive test depends on patient and technical factors; multiple methods may be required if initial approach fails. Tissue for sequencing/metagenomics may only be required if diagnosis has not been established by traditional methods. AFB, acid-fast bacilli; Ag, antigen; BAL, bronchoalveolar lavage; CMV, cytomegalovirus; IFA, indirect fluorescent antibody; PCR, polymerase chain reaction; VATS, video-assisted thoracoscopy.

TABLE 123-9 Routine Laboratory Evaluation of Bronchoalveolar Lavage and Biopsy Specimens in Immunocompromised Hosts

- **Tissue pathology**[a]
  - Wright–Giemsa stain
  - Papanicolaou stain
  - Silver stain
  - Modified Jimenez stain (or other suitable for detecting *Legionella*)
  - Fluorescent antibody stain for *Pneumocystis*
  - Organism-specific PCR: CMV, HSV, VZV, adenovirus, influenza, other respiratory viruses
  - Save specimen for 16S/18S PCR or metagenomic sequencing
- **Microbiology**[a]
  - Stains:

    - Wet mount KOH or calcofluor white
    - Acid-fast smear ± *M. tuberculosis* PCR
    - Modified acid-fast
    - Fluorescent antibody stain for *Pneumocystis*, *Legionella* (respiratory viruses if PCR unavailable)
  - Antigen/molecular:
    - Respiratory viral PCR testing: influenza, parainfluenza, rhinovirus, human metapneumovirus, SARS-CoV-2, adenovirus (antigen testing if PCR unavailable)
    - *Mycoplasma* and *Bordetella pertussis* PCR
    - *Pneumocystis PCR*
    - *M. tuberculosis PCR*
    - Galactomannan (BAL)
  - Culture:
    - Bacterial (aerobic), semi- or quantitative method
    - *Legionella* sp. (chocolate yeast extract)
    - Fungal—consider epidemiology: *Aspergillus*, *Cryptococcus*, *Histoplasma*, mucormycosis (do not grind when mucormycosis being considered)
    - Mycobacterial culture (tuberculosis and nontuberculous)
    - Nocardia/actinomyces

[a] *Available testing and stains will vary by laboratory. In all cases, close liaison with clinical microbiologists and pathologists regarding potential infective organisms will assist in ensuring that appropriate tests are performed. Test rationalization may be required where sample is limited.*

in Table 123-9. Communication directly with the microbiology laboratory regarding the most likely pathogen is helpful to ensure expeditious and efficient use of specimen, in addition to allowing specific sample processing requirements to be followed.

Sputum cultures can be useful and should be an initial test in all patients, although the yield is highest for bacterial pathogens. This simple, rapid test should be considered in all immunocompromised patients presenting with respiratory illness. Induced sputa have particular importance for *M. tuberculosis* and *Pneumocystis*, where there is greater yield than standard expectorated specimens.[156,157] Importantly, negative induced sputa does not exclude either of these diseases, especially *Pneumocystis* in HIV-negative patients.[158]

Bronchoscopy should be consider in all immunocompromised patients with unexplained respiratory presentations and suspected infection.[159] Whether bronchoscopy is required depends on the exact clinical circumstance and radiologic findings. However, this intervention is frequently necessary in patients with otherwise unexplained pulmonary presentations, given the variety of possible diagnoses (which can occur concurrently) and the difficulties associated with empiric therapy for opportunistic infections. Transbronchial biopsy should be considered, when risks are acceptable, as there is a potential increased yield in immunocompromised patients.[160–163]

Radiologically guided (usually via CT) percutaneous biopsy of lung or pleural lesions is an important intervention in immunocompromised patients with suspected pulmonary infection for whom a diagnosis has not been established using the previously described studies. This investigation is most commonly used to diagnose invasive fungal infection, but it also has important discriminatory power for differentiating fungal from other infections, including those due to mycobacterial disease and *Nocardia*. Additionally, percutaneous biopsy can aid in the diagnosis of malignancy and other noninfectious lung diseases.[164–169]

Open and video-assisted lung biopsy are final diagnostic tests that have the potential to obtain the most representative tissue, although potential risks must be carefully evaluated, as yield is variable.[170–177] These interventions have become less necessary as interventional radiologic techniques have improved.[178]

Blood cultures are useful in the majority of immunocompromised patients presenting with pulmonary infection, especially in acute presentations, where blood cultures are essential. In more subacute presentations, blood cultures positive for fungi (*Cryptococcus*, *Fusarium* sp., *Talaromyces marneffei*) or mycobacteria (both *M. tuberculosis* and nontuberculous mycobacteria) have significant therapeutic implications. When seeking to isolate tuberculosis or nontuberculous mycobacteria, specific mycobacterial blood cultures should be obtained and incubated long-term, given the potential slower growth of these organisms.

In all scenarios, a close working relationship with the microbiology and pathology laboratories provides the highest likelihood of success in identifying the causative organism. Laboratories have differing capabilities; liaison with microbiology and pathology colleagues regarding likely pathogens will assist in improving yield and turnaround time. Frequently, samples obtained may be limited and require rationing of testing to provide the highest yield.

SPECIFIC PULMONARY SYNDROMES IN IMMUNOCOMPROMISED HOSTS

While there is significant overlap of clinical syndromes between immunocompetent and immunocompromised hosts with a pulmonary presentation, some syndromes are more commonly encountered in immunocompromised hosts and warrant specific mention.

The combination of pulmonary and neurologic manifestations in immunocompromised hosts is notable. Findings may include a clear pneumonic process with concurrent meningitis, or a more subacute presentation of concurrently developing pulmonary and CNS mass lesions with minimal symptoms. Infectious causes of a "brain–lung" syndrome are outlined in Table 123-10. In such cases, diagnostics and imaging should be directed toward both sites, as a single diagnosis cannot always be presumed. Pulmonary investigations have been previously outlined and may provide a unifying diagnosis for both pulmonary and CNS manifestations. Specific, high-quality CNS imaging should always be considered in these presentations, including brain MRI, preferably with gadolinium contrast. In some circumstances, lumbar puncture for cytologic and microbiologic analysis of CSF may be useful, particularly if meningoencephalitis is suspected. When diagnostic uncertainty persists, biopsy of CNS lesions may be helpful, although the increased risks of the procedure must be considered.

In patients with concurrent pulmonary and skin manifestations, a broad differential diagnosis should be considered (Table 123-10). Skin biopsy is a generally safe and readily undertaken procedure

TABLE 123-10 Organisms Associated with Brain–Lung Syndromes and Skin–Lung Syndromes in Immunocompromised Hosts

Syndrome	Infectious Causes	Noninfectious Causes
Brain–lung syndrome	Disseminated viral infection (VZV, HSV, adenovirus, CMV) *M. tuberculosis* Nontuberculous *Mycobacteria* *Burkholderia pseudomallei* *Streptococcus pneumoniae* *Nocardia* sp. *Rhodococcus equi* *Coccidioides* sp. *Histoplasma capsulatum* *Cryptococcus* sp. *Aspergillus* sp. *Toxoplasma gondii* *Strongyloides stercoralis* (with Gram-negative meningitis)	Malignancy Autoimmune - Sarcoidosis - Granulomatosis with polyangiitis - Vasculitides Aseptic/thrombotic emboli

that can provide a rapid and specific diagnosis in many patients with rash and concurrent pulmonary pathology. In patients with vesicular or pustular lesions, a swab of vesicles or a pustule for Gram stain, culture (including bacterial, mycobacterial, *Nocardia*, and fungal cultures), and viral analysis (varicella zoster/herpes simplex via direct fluorescent antigen or PCR) can be particularly useful.

In both syndromes, the clinician must always consider the possibility that the processes occurring in separate organ sites are different and unique and may be infectious or noninfectious. This is especially true in immunocompromised hosts, in whom concurrent processes are common.

PULMONARY INFECTION IN LUNG TRANSPLANT RECIPIENTS

Lung transplantation is reviewed in detail in Chapter 106. When considering pulmonary infection, lung transplant recipients constitute a unique set of immunocompromised patients. As a group, they are often managed with more immunosuppression compared with other solid organ transplant recipients. In addition, their transplanted organ is a common site of infection and is constantly exposed to the environment. Lung transplant recipients with underlying cystic fibrosis are frequently heavily pretreated with antibiotics and, as a result, are colonized with multidrug-resistant bacteria and fungi. Thus, pretransplant colonizing organisms should be considered when designing prophylaxis and when considering potential pathogens.

The importance of establishing a specific diagnosis for a pulmonary process in lung transplant recipients cannot be overstated. The differential diagnosis almost always includes infection and rejection, with differentiation of the two guided mostly by histology and microbiological sampling. Atypical nonpulmonary pathogens also should be considered in lung transplant recipients. For example, pulmonary or disseminated infection with *Ureaplasma* species is associated with development of hyperammonemia syndrome after lung transplant and requires specific cultures or molecular testing for detection. This diagnosis can be challenging to recognize clinically, as the primary disease manifestations are those of hyperammonemia rather than infection.[179] Since prophylaxis is used more frequently, and often for prolonged periods in lung transplant recipients, empiric therapy must address the likelihood of breakthrough infection or development of resistant organisms.

Importantly, the surgical bronchial anastomotic site is highly susceptible to infection with potentially devastating consequences; hence, prophylaxis is often broad following lung transplantation. The bronchial anastomotic site is immediately exposed to the patient's environment and respiratory secretions. In addition, its blood supply is potentially impaired. Bronchial anastomotic infection is often diagnosed on routine bronchoscopy early in the posttransplant course. Later presentations include features of airway obstruction or bleeding. Commonly implicated organisms include fungi, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*.[180] Early debridement and aggressive antibiotic therapy are the mainstays of therapy.

Chronic lung allograft dysfunction is a disabling and irreversible cause of lung function decline in lung transplant recipients and includes two phenotypes: bronchiolitis obliterans syndrome (BOS) and restrictive allograft syndrome.[181] Respiratory viral infections and cytomegalovirus may be implicated in the etiology of chronic lung allograft dysfunction.[182–185] However, data are conflicting, and mechanisms are still being elucidated.[186] Clinical implications are currently unclear, although it appears reasonable to emphasize minimizing exposure risk and vaccinating when possible. Although treatment of viruses with effective therapy has yet to be proven effective in preventing chronic lung allograft dysfunction, treatment has been generally recommended when effective agents are available.[187] Reduction in immunosuppression is also limited in lung transplant recipients, for whom onset of rejection can be a life-threatening event. The importance of multidisciplinary care between pulmonary and infectious disease specialists cannot be overemphasized.

NONINFECTIOUS PULMONARY SYNDROMES

Immunocompromised hosts, for example, lung transplant recipients, patients with newly diagnosed acute myeloid leukemia, or chronically immunosuppressed patients with rheumatoid arthritis, are frequently complex. These patients have heightened risks not only for infection, but also for noninfectious pulmonary processes including malignancy, thrombosis, cardiac or renal failure, autoimmune phenomena, and drug toxicity (Chapter 94).

The occurrence of multiple, simultaneous infections or conditions often complicates and delays appropriate therapy. For example, CMV infection may complicate treatment of graft rejection or GVHD and contribute to the pathogenesis of *Pneumocystis* or *Toxoplasma* pneumonia. In the compromised host with fever and pneumonitis, chest radiographs may be difficult to interpret. Noninfectious causes of pulmonary infiltrates may coexist with infection, and atypical patterns predominate. Drug toxicities (e.g., bleomycin, cyclophosphamide, sulfa drugs), leukoagglutinin reactions, engraftment or immune reconstitution syndromes, radiation injury, pulmonary emboli, and lesions of metastatic cancer may coexist with opportunistic infection. The "typical" evolution of pulmonary infection may be altered by the presence of underlying (e.g., interstitial) pulmonary disease, as well as by diminished inflammatory responses. Commonly, laboratory tests may need to be repeated, CT scans performed, or invasive diagnostic modalities (including biopsy) utilized in the evaluation of patients unresponsive to therapy. Furthermore, complications of treatment may contribute to development of new infections or other complications. For example, trimethoprim/sulfamethoxazole may cause pneumonitis, hepatitis, or Stevens–Johnson syndrome; ganciclovir may cause neutropenia; transfusion reactions may cause pulmonary infiltrates and hemolysis; tacrolimus and cyclosporine may cause hemolytic–uremic syndrome; and antimicrobials may contribute to the development of thrush and *C. difficile* colitis.

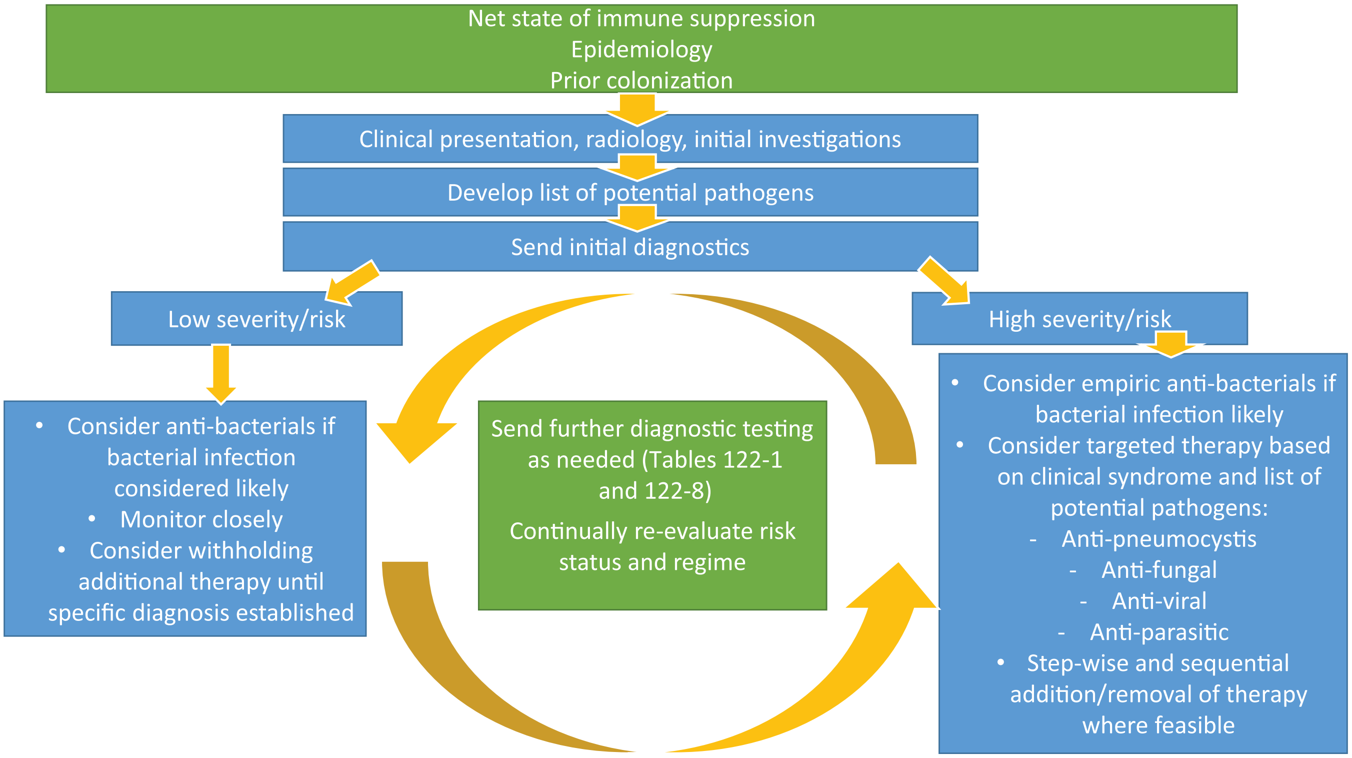
EMPIRIC ANTIMICROBIAL THERAPY

Empiric therapy for pulmonary infection is covered in detail in Chapter 125. Exact regimens for empiric therapy are beyond the scope of this chapter, but a framework for determining empiric regimes is discussed. Although the literature is still somewhat limited, some professional societies have published guidelines regarding empiric antimicrobial therapy in immunocompromised hosts.[188,189] Figure 123-11 describes a common approach to empiric therapy.

When considering empiric therapy in immunocompromised patients, epidemiologic exposures, prior colonization or history of infection, and the net state of immunosuppression should be considered in developing a list of potential pathogens. Clinical presentation, imaging, and initial diagnostics can be used to refine the list of potential pathogens. At this point, a risk stratification can be performed to determine to what extent organisms on the list need to be treated empirically.

Patients should be stratified into two groups: (1) those with low initial severity and low risk for decompensation without any, or with narrow, empiric coverage, and (2) those with high initial severity of disease or high risk of decompensation. By design, those with higher initial severity or risk of decompensation are likely to require broader initial empiric therapy.

In an era of rapid molecular diagnostics, many infections can be confirmed or excluded quickly. Despite this, risk stratification is necessary, since the need to ensure adequate initial antimicrobial coverage increases with illness severity and risk of decompensation. This approach is balanced against the underlying need to ensure sufficient opportunity to collect adequate initial samples and allow a reasonable chance of specific microbial diagnosis. This is particularly true for bacterial and nonviral infections, where diagnostic yield may be reduced following empiric therapy, and when empiric therapy may be associated with substantial toxicity. Notably, many prospectively



Net state of immune suppression
Epidemiology
Prior colonization
Clinical presentation, radiology, initial investigations
Develop list of potential pathogens
Send initial diagnostics
Low severity/risk
High severity/risk
• Consider anti-bacterials if bacterial infection considered likely
• Monitor closely
• Consider withholding additional therapy until specific diagnosis established
Send further diagnostic testing as needed (Tables 122-1 and 122-8)
Continually re-evaluate risk status and regime
• Consider empiric anti-bacterials if bacterial infection likely
• Consider targeted therapy based on clinical syndrome and list of potential pathogens:
- Anti-pneumocystis
- Anti-fungal
- Anti-viral
- Anti-parasitic
• Step-wise and sequential addition/removal of therapy where feasible

Figure 123-11 Approach to empiric therapy for pulmonary infections in immunocompromised hosts. Following consideration of the patient's net state of immunosuppression, prior colonization, and epidemiologic exposures, a list of potential causative pathogens can be developed. Initial diagnostics should be sent as soon as possible, including blood cultures, sputum cultures, serum/urine testing, and molecular testing. Patients can be categorized as high- or low-risk, based on severity of current illness and risk of further deterioration. Empiric therapy should be targeted to most likely causative pathogens. In low-severity/risk patients, consider delaying or narrowing empiric therapy to maximize likelihood of achieving a specific diagnosis. In high-severity/risk patients, it may be less feasible to delay empiric therapy while diagnostics are underway, and broader empiric therapy may be required. In all patients, the goal of specific microbiologic diagnosis is paramount (Fig. 123-10); yield may be higher in low-severity/risk patients, in whom empiric therapy is delayed or narrower. In both high- and low-severity/risk patients, constant re-evaluation of regimen efficacy and safety is warranted, as is regimen refinement as diagnostic tests return. Where feasible, stepwise and sequential introduction and withdrawal of agents may prove useful.

TABLE 123-11 Factors Involved in Determining Risk Category for Empiric Therapy

Considerations when determining pulmonary infection severity and risk for decompensation

- Hemodynamic status
- Oxygenation, respiratory rate, and pulmonary reserve
- Background patient "frailty" (malnutrition, deconditioning, age, etc.)
- The net state of immune suppression
- Degree of systemic compromise (confusion, renal failure, liver failure, cardiac failure)
- Recent hospitalization or surgical intervention, including transplantation
- Neutropenia
- Degree of inflammatory response by bedside, laboratory, and radiographic criteria
- Previous infections, including with opportunistic pathogens ("susceptibility" to infection)
- Recent epidemiologic exposures to respiratory pathogens

validated measures of pneumonia severity (e.g., Pneumonia Severity Index [PSI], CURB-65), have excluded many immunocompromised hosts, including solid organ and stem cell transplant recipients.[190–192] Thus, risk stratification is in the hands of the bedside clinician, and formal criteria do not exist. Factors to consider when determining risk stratification are listed in Table 123-11.

Once patients are categorized as low- or high-risk, the urgency and breadth of empiric therapy can be determined. The underlying principle of striving to obtain a specific diagnosis should be held paramount in "low-risk" patients, in whom tailoring empiric therapy to the most likely pathogens can be undertaken with minimal negative consequences. In higher-risk patients, the threshold for initiating empiric therapy is lower and may supersede the goal of establishing a specific diagnosis or initiating empiric therapy prior to diagnostic evaluation.

Frequently, a clinician's approach to empiric therapy is "step-wise and sequential." Initial therapy may be targeted toward the most likely pathogens, based on the previously described approach. These pathogens are frequently bacteria. Once the initial empiric regimen is instituted, clinical progress should be carefully monitored. As the patient progresses and diagnostic test results return, additional therapeutic agents (e.g., antiviral, antifungal, or antiparasitic drugs) can be added. The threshold for adding a new agent depends on the patient's risk category and clinical progress, and the clinician's diagnostic certainty.

Finally, utilization of previous antimicrobial exposure, including prophylaxis regimens, must be considered. Generally, infection emerging while a patient is on a prophylactic agent indicates drug resistance, and the agent should be avoided in empiric regimens.

■ Antibacterials

The threshold for initiating empiric therapy for bacterial infection should be low, given the risk of rapid deterioration due to bacterial sepsis and the ability to rapidly obtain blood and sputum cultures. Empiric antibiotic regimes should be selected based on local antibiograms and consideration of the patient's own microbial flora. Immunocompromised hosts are regularly "healthcare exposed" and are at higher risk for multidrug-resistant organisms. In addition, a documented history of these infections should further inform antibiotic selection.[189] Atypical pathogens (e.g., *Mycoplasma*, *Legionella*) should be considered when community acquisition of bacterial pneumonia is likely.

The initial antibiotic regimen design must also take into account special clinical circumstances. For example, the presence of neutropenia should prompt broader empiric coverage consistent with a "febrile neutropenia" addressed in local clinical guidelines. Typically, such regimens include an antipseudomonal agent. Similarly, a regimen for a patient with concurrent pulmonary and neurologic components may warrant antibiotics suitable for empiric treatment of meningitis or encephalitis, including drugs that cross the blood–brain barrier.

Typically, antimycobacterial agents are withheld until sufficient diagnostic testing has been performed. Sufficient diagnostic evaluation prior to initiation of antimycobacterials is vital to successful management of these patients, given the need for prolonged therapy and the potential for drug resistance. Frequently, test results may not be available for weeks, and empiric therapy may be initiated in a patient with a high pretest probability for a mycobacterial infection. Finally, empiric therapy for *Nocardia* and *Toxoplasma* may be clinically indicated based on the patient's clinical or microbiology specimen stains, ideally after sufficient diagnostic specimens have been sent.

While tempting, empiric antibacterial therapy must not be excessively broad, given the risks that prolonged use of such agents can pose. The risk of *Clostridioides difficile* and emergence of multidrug-resistant pathogens is already heightened in many immunocompromised patients, owing to multiple hospital admissions, increased antibiotic use, and immunosuppressive medications. The delicate balance between early, empiric, broad-based antibiotic coverage and the hazards of such an approach underscores the importance of determining a specific diagnosis as expeditiously as possible.

■ Antivirals

Empiric antiviral therapy is less commonly required, since rapid and accurate molecular testing allows relatively prompt diagnosis or exclusion of many pathogenic viruses in immunocompromised hosts. When diagnostic results are delayed, pretest probability is high, or the patient is very ill, empiric antiviral therapy for likely pathogens may be required. Empiric therapy for influenza is frequently started in suspected cases, pending molecular testing. SARS-CoV-2 represents a potentially severe respiratory infection, treatment of which entails evolving therapeutic options that may be warranted empirically as evidence emerges. Empiric therapy for herpes simplex, varicella zoster, or CMV is occasionally required, depending on the clinical circumstances. Other antiviral therapy options are limited and are frequently associated with greater initial toxicity; hence, empiric therapy in the absence of a clear diagnosis may be unwarranted.

■ Antifungals

Institution of empiric antifungal therapy is a complex decision, and involvement of an expert is usually necessary. Careful consideration via the approach outlined in Fig. 123-11 is recommended.

The risk of reducing the yield of diagnostic cultures is balanced against the risk of clinical deterioration and progression of infection. The complexity of decision-making is intensified, as many fungal infections require prolonged treatment (sometimes for months or even years) with drugs that are often associated with toxicities and drug interactions. These factors warrant a timely diagnostic investigation, including establishing a specific diagnosis and antifungal susceptibilities. Higher-risk patients, or those with fungal infections that appear rapidly progressive or disseminated, warrant earlier empiric therapy, regardless of the timeline for results of diagnostic tests. Conversely, some fungal infections may have a subacute course. In lower-risk patients, delaying antifungal treatment until diagnostics are performed may be reasonable. An example of an infection that requires urgent empiric antifungal therapy is mucormycosis; another is cryptococcal meningitis. Mucormycosis has the potential for rapid progression and dissemination and must be treated as a medical emergency using a combination of medical and surgical approaches. The clinical presentation of cryptococcal meningitis is dominated by neurologic features and is rapidly diagnosed using cryptococcal antigen testing.

Empiric treatment for *Pneumocystis jirovecii* is often required, particularly in patients with untreated HIV infection or other forms of profound immunosuppression (especially those not on prophylaxis). Frequently, patients with *Pneumocystis* present with severe pneumonia and require urgent treatment prior to results of testing. The decision to start empiric anti-*Pneumocystis* therapy must take into account the net state of immunosuppression (the "right" host for *Pneumocystis*), the clinical presentation (e.g., hypoxia disproportionate to other respiratory findings; a large arterial–alveolar oxygen gradient; an elevated LDH), and compatible imaging (i.e., diffuse ground-glass opacities). An appropriate combination of findings in a patient at risk usually creates a pretest probability high enough to warrant empiric therapy prior to a establishing a definitive diagnosis.

DRUG INTERACTIONS AND DISTRIBUTION

When prescribing antibiotics, possible drug interactions are an important consideration, particularly in immunocompromised hosts, who frequently take medications with numerous interactions (e.g., calcineurin inhibitors [tacrolimus, cyclosporine], ritonavir). Azole antifungals are commonly used in immunocompromised hosts; other antibiotics, such as clarithromycin and rifampicin, also are problematic. The involvement of an experienced clinical pharmacist is invaluable. Consideration of antimicrobial penetration to the site of action is important in regime selection. Some antibiotics have poor activity in the lung (e.g., daptomycin, which is inactivated by alveolar surfactant), have poor clinical efficacy for blood stream infection (e.g., tigecycline), or do not cross the blood–brain barrier easily (e.g., cefazolin).

Some antimicrobials should be prescribed only in conjunction with a plan for therapeutic drug monitoring. This is especially true for oral agents (for which absorption may be variable) and agents with narrow therapeutic indices. Vancomycin, aminoglycosides, flucytosine, voriconazole, and posaconazole are commonly used antimicrobials whose therapeutic drug levels inform guidance on drug dosing.

ALLERGY AND DRUG INTOLERANCE

Immunocompromised hosts are frequently exposed to healthcare settings and antimicrobial agents. Consequently, antibiotic and drug allergies are frequently reported among this population.[193,194] Adequate investigation and documentation of the precise nature of the drug reaction, including possible allergy testing, is vital to ensuring that adequate antimicrobial therapy is available, if needed. Ideally, clinicians should perform an allergy evaluation when the patient is well, thereby obviating the need for testing in the setting of acute illness.[194]

IMMUNOSUPPRESSION REDUCTION AS THERAPY

An improvement in the "net state of immunosuppression," either by reduction of immunosuppressive medications or by restoration of immune function (e.g., via initiation of antiretroviral therapy for HIV) may represent important primary or adjunctive therapy in immunocompromised hosts with infection. The timing and degree of immune reconstitution must take into account potential risks and benefits.[57]

For infections without availability of high-quality antimicrobial therapy, immunosuppression reduction may be potentially lifesaving (e.g., mucormycosis). However, reduction of immunosuppression carries risks in some hosts—for example, triggering a flare of an underlying autoimmune condition that may ultimately require *more* immunosuppression to control. The risk is especially great in transplant recipients, in whom immunosuppression reduction may precipitate allograft rejection or graft-versus-host disease that can be life-threatening.

Another risk of immunosuppression reduction is the emergence of immune reconstitution syndrome, as described below.

Thus, for some infections, reduction in "net state of immunosuppression" may be warranted until specific antimicrobial therapy is given, for example, treatment of cryptococcal meningitis in patients with HIV infection and decreased CD4 count who are not already on antiretroviral therapy.[23] In all cases, complex treatment decisions should be made following discussion with experts in management of the underlying condition and infectious disease consultants.

IMMUNE RECONSTITUTION SYNDROME: A DIAGNOSIS OF EXCLUSION

Immunocompromised hosts may experience an inflammatory syndrome that complicates therapy for infection or unmasks a new infection with immune recovery. *Immune reconstitution inflammatory syndrome* refers to a vigorous immune response to a pathogen and is typically associated with some degree of recovery in immune function. The syndrome has been described in patients with HIV infection as they begin antiretroviral treatment and experience a rise in CD4+ T cells.[195,196] However, it has also been described in patients recovering from neutropenia, solid organ transplant recipients, and others undergoing withdrawal of immunosuppression.[195,197,198]

A classic example is a patient with HIV infection who presents with a low CD4+ T cell count and concurrent tuberculosis. With commencement of antituberculous therapy, improvement or stabilization of symptoms may be noted. However, as antiretroviral therapy–related effects develop, recovering T cells recognize the tuberculosis pathogen and generate an immune response, manifest as fever, constitutional symptoms, and radiographic worsening of pulmonary infiltrates. In addition, local inflammation may occur at sites of infection that were previously unrecognized or that had stabilized or improved.

Other examples of immune reconstitution inflammatory syndrome include recovery of neutrophil counts with engraftment following hematopoietic stem cell transplant or with reduction of immunosuppression following solid organ transplant.

Key to patient management in these circumstances is consideration of the patient's entire clinical course to date. Careful bedside assessment is required to ensure that the diagnosis is correct (which may require repeat clinical evaluation and laboratory sampling) and reassessment for development of new processes (infectious and noninfectious, including drug reactions). The clinician must consider the possibilities that a new process has developed, or a new process *and* immune reconstitution are present. In some circumstances, additional immunosuppression may be warranted if immune reconstitution is the predominant clinical problem.[199]

OCCAM'S RAZOR MAY NOT APPLY

Immunocompromised hosts may experience multiple concurrent processes, some of which are infectious and others noninfectious. Additionally, *multiple concurrent* infections may be observed. For example, consider a hematopoietic stem cell recipient with graft-versus-host disease involving the lungs who develops CMV infection, followed by a fungal lung infection. All three issues are important and require therapy. A clinician managing such a patient must be mindful that establishing one diagnosis does not exclude all others. Careful monitoring of the patient's progress is required, as multiple diagnoses may emerge through the course of an illness.

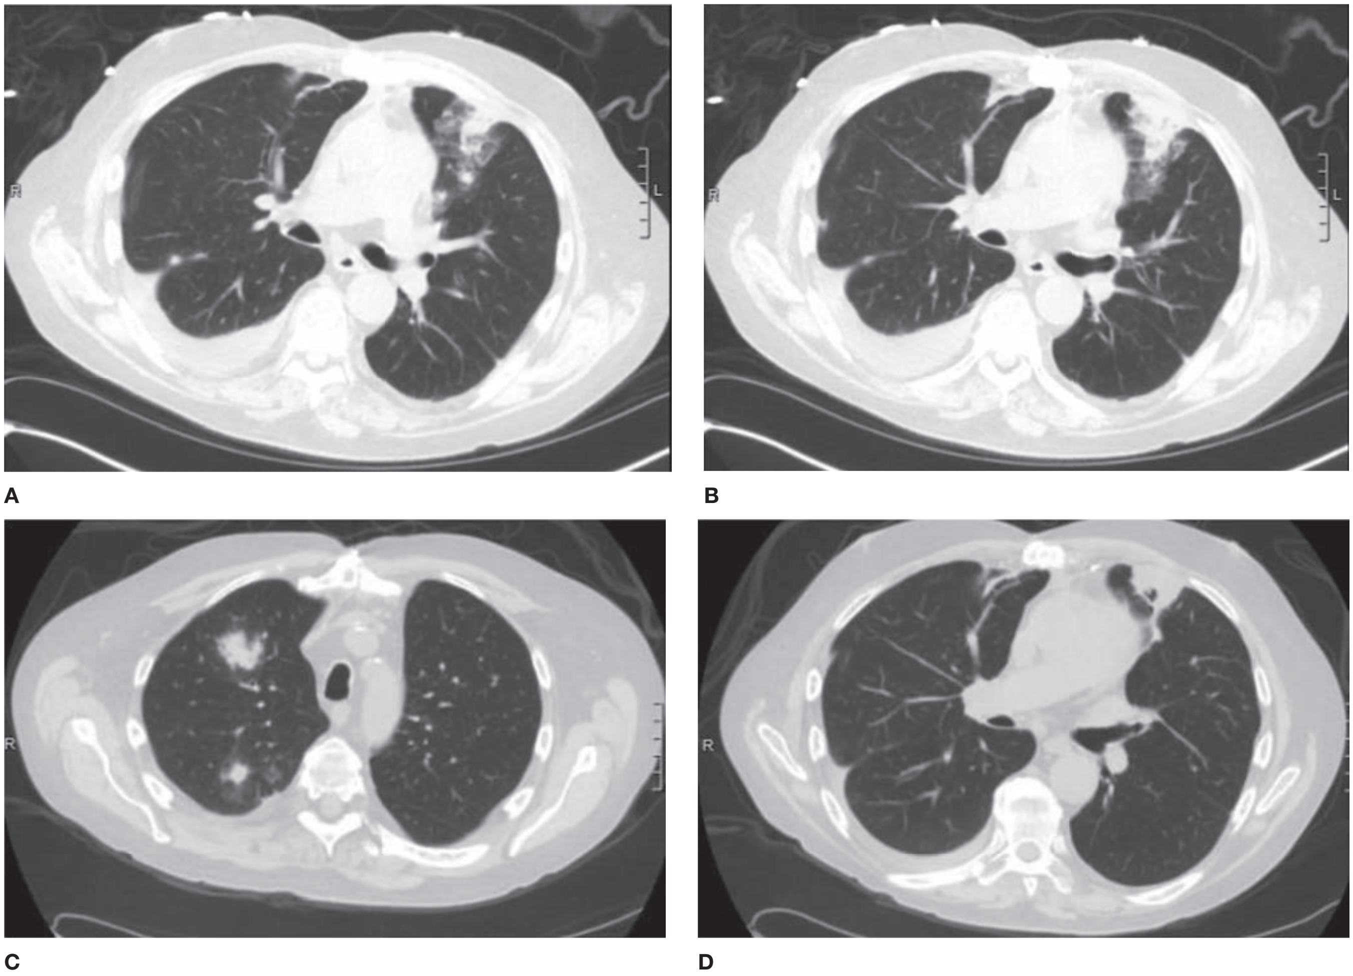


Figure 123-12 A recent cardiac transplant recipient developed CMV DNAemia, quickly followed by left lower lobe pulmonary aspergillosis with *Aspergillus flavus* (**A** and **B**). While on valganciclovir and voriconazole (therapeutic drug levels), a new right upper lobe pulmonary lesion developed on surveillance CT chest at 4 weeks (**C**), while the left lower lobe lesion was improving and starting to cavitate (**D**). Bronchoscopy showed a necrotic bronchial lesion. Bronchial biopsy demonstrated aseptate fungi. Lobectomy pathology demonstrated abundant septate and aseptate fungi, as well as CMV viral inclusions. Cultures grew *Scopulariopsis* species, *Nocardia nova*, and multidrug-resistant *Enterobacter*. Fungal polymerase chain reaction of pulmonary tissue demonstrated *Rhizopus oryzae* and *Aspergillus niger*. The patient was treated for pulmonary infection with CMV, multidrug-resistant *Enterobacter cloacae*, *Nocardia nova*, *Scopulariopsis* species, *Aspergillus*, and *Rhizopus oryzae*; immunosuppression was reduced. The patient eventually made a full recovery. This case demonstrates that multiple simultaneous process may occur, and that specific microbial diagnosis is key to successful management.

Constant vigilance is vital to the management of the immunocompromised host with infection (Fig. 123-12).

CHAPTER 124

Microbial Virulence Factors in Pulmonary Infections

Carl D. Britto
Gregory P. Priebe
Gerald B. Pier

GENERAL CONSIDERATIONS

Beginning at birth, microbial organisms enter and leave the human body, primarily through external and mucosal surfaces. Some of these predominantly commensal organisms become resident; others are transient; and still others establish latent foci in various tissue spaces. Over a lifetime, the host–pathogen interactions that take place in an average human determine colonization, microbiome composition, and susceptibility to infections as well as immune-related events such as vaccine responses, autoimmunity, and malignant transformation. The human host is a reservoir for hundreds of strains of viruses, thousands of bacterial species, and a scattering of fungi and parasites. When these organisms violate their niche, invade, or produce toxic products, and at the same time overcome innate and adaptive host defenses, virulent interactions take place and can lead to disease. Organisms have evolved a variety of strategies to overcome host defenses, evade the immune system, scavenge for nutrients, eradicate competing bacteria, and survive to spread to other hosts. At the macro level, infection in the lung is the culmination of a disruption in the epidemiologic triad comprising host, agent, and environment. At the molecular level, new mechanistic insights into the interactions between host susceptibility, pathogen virulence, and environmental risk factors continue to be discovered.

The immune system maintains surveillance for organisms that invade phagocytes, propagate, and resist killing, and also for organisms that invade nonphagocytic cells. Means by which microbes can be controlled range from physical clearance mechanisms, to phagocytosis (followed by oxidative or nonoxidative killing), to nutritional depletion (e.g., sequestration of iron, which is an essential nutrient for bacterial growth). The existence of heavy colonization or infection in the upper airways increases the potential for infection in the lungs by a variety of mechanisms, mostly by a simple dose effect, whereby a large burden of potentially pathogenic organisms overwhelms the clearance mechanism of the lungs. Although the alveolar spaces are generally sterile, low levels of microorganisms are continually inhaled into the lungs. Inoculation of the lungs can occur from a variety of sources, including aspirated oropharyngeal secretions, directly inhaled from ambient air (airborne) or as droplet nuclei, particularly in closed environments, where density is great and infected individuals can deposit organisms into the air. Although not common, organisms can also gain entry into the lung via hematogenous spread from the bloodstream to the lungs, perhaps most notably in Lemierre disease related to septic thrombophlebitis due to the Gram-negative anaerobe *Fusobacterium necrophorum*.

The quantity and species diversity of many of the organisms colonizing the upper airways can be stable over long periods, although transient colonization with a variety of microbes also occurs with some frequency, and these changes are often correlated seasonally and/or with concomitant infections with respiratory viruses. For example, *Streptococcus pneumoniae* (pneumococcus) and *Neisseria meningitidis* (meningococcus) are more frequently isolated from the nasopharynx or throat during the winter months.[1–4]

Whether these inhaled or aspirated microbes cause disease depends on the intersection of multiple factors, one of which is whether the microbe possesses and expresses virulence factors. The regulation of the expression of bacterial virulence factors is tightly controlled by the interplay of pathogen factors including a complex network of two-component regulatory systems and pathogenicity islands. In *Pseudomonas aeruginosa*, quorum sensing (cell density–dependent gene expression) via small organic molecules called acyl homoserine lactones has been shown to be important for virulence in pneumonia models both by regulating expression of secreted toxins and by inducing inflammation.[5] *Staphylococcus aureus* strains control virulence through regulatory peptides involved in activating and suppressing the accessory gene regulator *(agr)* network, with similar systems found in other Gram-positive pathogens as well.[6] Interfering with these systems with appropriate inhibitors holds promise for future therapeutic interventions in bacterial pneumonia.

Most of the initial host response to pathogens in normally sterile sites, indicative of infection, involves the basic inflammatory responses of innate immunity. The microbes generally initiate this response by activating complement, binding quasi-specific host molecules such as mannose-binding lectin, and generating other tissue signals via cell-associated pattern-recognition molecules such as the TLRs[9,10] that lead to an influx of inflammatory cells and serum factors into the site of infection (Chapter 120). Inflammation leads to clinical symptoms such as sore throat, sneezing, coughing, malaise, and so on. Some particularly virulent microbes can rapidly produce much more serious disease as the organisms spread and cause inflammation diffusely throughout the respiratory tract. The balance between the host inflammatory response and microbial growth is the key factor in the disease process. As is often the case with microbial infection, inflammation is a double-edged sword, critically important for resolution of infection but also responsible for tissue damage.

THE ROLE OF THE MICROBIOME

The respiratory tract harbors distinct communities of microbes, with multiple discrete ecologic niches (e.g., nasal cavity, oropharynx, upper airways, lower airways) that vary in terms of temperature, pH, oxygen tension, mucus production, and other factors. With advances in sequencing technologies and bioinformatic capabilities, novel paradigms in understanding susceptibility to infections in relation to the microbiome continue to emerge. Perhaps the most important source of organisms causing pneumonia is the flora of the upper respiratory tract. A large microcosm of organisms that includes both pathogenic and nonpathogenic bacteria and fungi normally resides in the upper airways. These organisms are in a state of dynamic equilibrium and influence the susceptibility of infections based on the changing composition of the microbiome (Chapter 121). Bacteria colonizing the nasopharynx are often associated with the concurrent presence of certain viruses and bacteria—for example, *S. aureus* is associated with influenza but not rhinoviruses or pneumococcus; and pneumococcus with rhinoviruses, *Haemophilus influenzae*, and *Moraxella catarrhalis*.[7] The detection of rhinovirus together with *M. catarrhalis* has been associated with more severe manifestations of bronchiolitis. Human respiratory syncytial virus (RSV) infection predisposes to a respiratory microbiota that is *Streptococcus*-dominant, while infection with rhinovirus predisposes to a *Haemophilus*-dominant profile.[8] RSV infection has been shown to be enhanced by preceding *S. pneumoniae* infection both in vitro and in vivo,[9] but preceding RSV infection induces antibacterial effects by overexpression of proteins with known antibacterial activity.[10] In mice, colonization of the upper respiratory tract with *S. aureus* drastically reduces influenza-induced acute lung injury and mortality by recruiting a C-C chemokine receptor type 2+ (CCR2+) monocyte subset to the lungs and inducing an M2 macrophage phenotype.[11] However, increased diversity of the nasopharyngeal microflora may increase influenza severity, and severe influenza can decrease the abundance of *S. aureus* while increasing the abundance of *Prevotella*, *Streptobacillus*, *Porphyromonas*, *Granulicatella*, *Veillonella*, *Fusobacterium*, and *Haemophilus*.[11]

Organisms that make up the normal microbial flora in other parts of the body can be transferred to the lung, where they can cause infection. In early-onset group B streptococcal pneumonia and sepsis in neonates, the organisms are transferred during birth from the vaginal canal of the mother to the respiratory tract of the infant. In some cases, as long as a potential pathogen confines itself to a local site in the upper respiratory tract, no disease will ensue. At other times, growth at the local site and/or elaboration of toxins can cause frank disease; this is the mechanism of group A streptococcal pharyngitis and whooping cough caused by *Bordetella pertussis.* In general, the nasopharynx and throat readily tolerate the presence of a dynamic bacterial population, comprising mostly nonpathogenic strains along with potential pathogens that often come and go quietly, not spreading to other tissues or causing disease except when other factors intersect, such as a respiratory viral infection or other types of host stressors. While the microflora of the anterior nares and the nasopharynx are distinct, there is considerable overlap between the bacterial community compositions from these two anatomic sites, and microflora disease predictor associations from the nasopharynx are recapitulated in the anterior nares.[12]

OVERCOMING INHERENT PHYSIOLOGICAL AND CHEMICAL BARRIERS

Organisms gain access to the lower airways, either alone or in association with particles of mucus. They are generally either cleared by mucociliary flow or scavenged by phagocytes (Chapter 6). Particulates greater than 10 μm in diameter settle in the larger airways. Particles less than 5 μm that are not cleared within the larger airways reach the alveoli. Most particulate matter is not infectious, and only viable spores or organisms can cause infection. Prior to entering the lower respiratory tract, an organism must overcome a number of inherent mechanical and chemical barriers in the nasal passages and upper respiratory tract. The mucous lining of the respiratory tract possesses a variety of protective entities that act as physical barriers as well as immune mediators of protection. Pathogens, through natural selection, have evolved mechanisms to evade these innate barriers. The capsule present on bacteria such as *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* reduces entrapment in the mucus and prevents adherence to epithelial cells to avoid activation of innate immune pattern recognition molecules such as toll-like receptors (TLRs). Thus, while there are studies using cell cultures that have shown that microbial adhesin factors such as choline-binding protein A (CbpA, also referred to as PspC or SpsA) promote pathogen binding to epithelial cells, and levels of pre-existing cross-reactive immunoglobulin to SpsA correlate with susceptibility to the establishment of pneumococcal carriage,[13] in vivo studies point to avoidance of epithelial binding and activation of innate immunity as correlates of pathogen virulence. For invasive pathogens, such as *S. pneumoniae*, the cell-wall phosphorylcholine has been shown to bind to the G protein–coupled platelet-activating factor receptor (PAFr) following inflammatory activation of human cells.[24] While this mechanism has been reported to lead to escape through the lung epithelium via the vascular endothelium into the circulation to cause sepsis, in vivo studies in mice showed that inhibition of binding of *S. pneumoniae* to PAFr by a receptor antagonist gave a contradictory outcome, increasing levels of *S. pneumoniae* in the lung and blood. It has been reported that type 1 and type 3 fimbriae of *K. pneumoniae* can extend beyond the capsular matrix and mediate D-mannose–sensitive adhesion to host epithelial cells, immune cells, and abiotic surfaces.[14] However, as was found with *S. pneumoniae* in vivo, *K. pneumoniae* avoids epithelial cell adherence to facilitate pathogenesis. *P. aeruginosa* possesses a protein called FliD at the tip of the flagellum that mediates adherence to respiratory mucin,[15] and *H. influenzae* similarly uses its pilus to bind to mucins[16] and anchor the cells within the respiratory tract. Most viruses and intracellular bacteria require attachment onto cells and subsequent intracellular invasion via structures that determine species and tissue tropism, transmissibility, and replication as typified by the viral hemagglutinin molecule on the surface of the influenza virus, the spike protein of SARS-CoV-2, the nucleocapsid of RSV, and the knob domain of adenovirus.[17,18] In contrast, intracellular nonviral microbes such as *Chlamydia* are taken into cells nonspecifically by phagocytosis or endocytosis.

Other extracellular pathogens that cause lung infections establish themselves in tissues by binding to factors in the mucus, notably mucin. Several bacterial pathogens that frequently cause pneumonia—including *P. aeruginosa, H. influenzae, S. aureus, S. pneumoniae, K. pneumoniae,* and some *Escherichia coli* strains—bind specifically to terminal or internal GalNAc-β (1–4)-Gal sequences lacking sialic acid residues commonly found on cellular glycolipids in the respiratory tract. *P. aeruginosa* has been prominently studied in regard to binding to respiratory mucins as a mechanism to establish and maintain infection in the lung. Nontypeable *H. influenzae* also appears to utilize pilus-mediated adherence to human respiratory mucins to establish chronic infections in the lung. *Bordetella pertussis* binds exclusively to the cilia on ciliated respiratory epithelium, using at least two bacterial cell surface factors, designated pertactin and filamentous hemagglutinin (FHA). A fraction of the organism's cell wall, the muramyl dipeptide, is then extensively produced and secreted, and this factor is toxic to the ciliated tracheal cells. These cells are extruded from the epithelial surface, perhaps in an attempt to clear the bacteria from the respiratory tract. With viruses, factors such as the neuraminidase and hemagglutinin proteins on the coat of the influenza virus are needed to promote viral shedding from infected cells followed by binding to uninfected cells, which leads to subsequent cellular invasion, viral replication, inflammation, and disease.

Microbes become "parasitic" when they express the requisite *virulence determinants* to gain entry and overcome or evade host defenses. In the absence of inherent host defenses, as seen with cystic fibrosis, in immotile cilia syndrome, and during prolonged endotracheal intubation, organisms are able to gain entry as well as colonize the respiratory tract more efficiently. Once these host barriers are breached, the downstream host immune responses are deployed to fend off infection.

SUBVERSION OF THE INNATE AND ADAPTIVE IMMUNE SYSTEM

The innate arm of the immune system is the evolutionary result of millions of years of exposure to pathogenic organisms. A variety of nonspecific innate immune mechanisms are potently activated by microbial binding to epithelial surface or, following binding and internalization, binding to intracellular Toll-like receptors (TLRs) and other conserved pattern-recognition molecules such as the complement system. Along with induction of cytokine synthesis and release there is a rapid activation of beneficial inflammation and clearance. Since the rates of evolution and natural selection of pathogenic organisms are infinitely greater than the innate immune system of humans, pathogens have evolved methods to evade these innate immune mechanisms. Thus, the microbes have a clear genetic advantage leading to selection of microbial factors that enhance virulence and survival.

Most of the initial host response to pathogens in normally quiescent tissues, indicative of infection, involves the basic inflammatory responses of innate immunity. The microbes generally initiate this response by activating complement, binding quasi-specific host molecules such as sugar-specific lectins, and generating other tissue signals via cell-associated pattern-recognition molecules such as the TLRs[19,20] that lead to an influx of inflammatory cells and serum factors into the site of infection (Chapters 19 and 120). Even the complement system can be inhibited by pathogen-specific effectors. For example, a staphylococcal complement inhibitor acts directly on C3 convertases (C4b2a and C3bBb), decreasing phagocytosis and killing by neutrophils,[21] and *N. meningitidis* produces a factor H binding protein to inhibit the killing activity of the complement system. Notably, this family of proteins accounts for part of the two available vaccines for the serogroup B strains of *N. meningitidis*.

Once a microorganism gains access to the lower respiratory tract, it must be able to resist clearance from this space, remain viable, and multiply. Organisms will either multiply locally, resisting local defenses, or spread to other body sites by traversing epithelial barriers that normally inhibit microbial spread. In order for extracellular organisms to multiply, they must scavenge for nutrients. Of particular note is the universal requirement for iron, which must be extracted from iron-binding molecules such as transferrin. Bacteria such as *K. pneumoniae* produce iron-binding substances known as siderophores that have an affinity for iron of greater than 10^{18} M and bind to high-affinity receptors on the bacterial surface. Organisms must also resist opsonophagocytosis or be able to survive and multiply within phagocytes. Viruses and obligate intracellular parasites, such as *Chlamydia*, usually must find their way to the lower respiratory tract and invade a specific cell in order to start growing. Some bacterial pathogens, such as *Legionella pneumophila* and *Mycobacterium tuberculosis*, need to encounter alveolar macrophages where they are ingested but resist destruction within these cells in order to establish infection and cause disease. *Mycobacterium tuberculosis* enters these cells in the lower and middle airways with high airflow, as it is an obligate aerobic organism (Chapter 130). Bacterial ligands and cellular receptors involved in this process are not fully characterized, although dendritic cell–specific intercellular adhesion molecule-3 grabbing nonintegrin (DC-SIGN) on dendritic cells and macrophages appears to play a role.[22] Following inhalation, most individuals will effectively clear or contain the tubercle bacilli, while in a minority the bacteria escape from the macrophage phagolysosome, or prevent its formation in the first place, leading to bacterial growth and host inflammation and resulting in lesions typical of tuberculosis. On the opposite side of the time spectrum from *M. tuberculosis*, inhaled spores of *Bacillus anthracis* as well as the *Listeria monocytogenes* and *Yersiniapestis* organisms are phagocytosed by alveolar macrophages but then escape from phagosomes, replicate within the cytoplasm, and emerge from the macrophage to enter the lymphatics or the bloodstream, with rapid development of clinical symptoms.[23]

Disease entities that result in the deficits in the innate arm shed light on host–pathogen interactions at this level. For example, in neutropenic mice, the infectious dose of *P. aeruginosa* applied to the nose of an anesthetized animal that produces a lethal pneumonia and sepsis can be in the range of 10 to 50 bacterial cells, whereas in a neutrophil-sufficient setting usually 107 to 108 bacterial cells are needed to initiate infection.[24] Clearly, avoiding polymorphonuclear leukocyte (PMN)-mediated clearance initiated by innate immunity is essential for serious pulmonary disease due to *P. aeruginosa*.

Many bacterial respiratory pathogens, particularly *B. pertussis*, *P. aeruginosa*, and *S. aureus*, produce very potent toxins. *P. aeruginosa* secretes elastase, an enzyme that can interfere with innate immunity in the lung by cleaving surfactant protein D, thereby abrogating its role in bacterial clearance.[25] Secreted toxins can act locally and/or systemically spread to cause clinical symptoms. The pertussis toxin is composed of two subunits, designated A and B; the B subunit binds to receptors on host cells, allowing the A subunit to enter the cell. The A subunit transfers the ADP-ribosyl part of NAD to a membrane-bound, GTP-binding protein that normally inhibits the enzyme adenyl cyclase. This leads to increased synthesis of cAMP and inhibition of neutrophil recruitment, thereby delaying antibody-dependent clearance of the bacterium even in immune hosts.[26]

The potential for epithelial injury to initiate tissue destruction can be a devastating consequence of microbial growth in normally sterile lung sites. In addition to toxins secreted extracellularly, protein effectors of the type III secretion system of *P. aeruginosa* can be directly injected into host cells, injuring the alveolar epithelium and subsequently allowing the release of proinflammatory cytokines such as TNF-α into the circulation, resulting in septic shock. *P. aeruginosa* also possesses a type VI secretion system that lyses nearby bacteria, allowing it to dominate its local environment.[27] The emergence of strains of community-acquired methicillin-resistant *S. aureus* (MRSA) associated with severe cases of necrotizing pneumonia appears to be related to elaboration of high levels of the alpha-hemolysin toxin (also called α-toxin), which injures epithelial cells after binding to a specific receptor, the zinc-dependent metalloprotease ADAM10.[28] The increased virulence of these MRSA strains was initially attributed to the Panton–Valentine leukocidin (PVL),[29] a pore-forming toxin specific for white blood cells, but subsequent work has shown that the PVL-producing strains are relatively rare causes of systemic infection[30] and these genes are mostly a marker for strains causing skin and soft-tissue infections with no real role in pneumonia.[31,32] The Gram-negative endotoxin, also called lipopolysaccharide (LPS), can cause serious damage to lung tissues, although the lung seems relatively resistant to the effects of inhaled endotoxin when compared with the systemic response to circulating LPS.

Many respiratory bacterial pathogens are encapsulated—a critical factor in promoting bacterial resistance to phagocytic killing. Neutralization of this antiphagocytic property by specific antibody results in high-level host immunity. Successful vaccines against *S. pneumoniae*, *H. influenzae* type b, and certain serogroups of *N. meningitidis* have been developed by engendering capsule-specific immunity via immunization, and comparable vaccines and monoclonal antibodies against *P. aeruginosa*, *K. pneumoniae*, group B streptococcus, and *S. aureus* are in various stages of development and testing in humans. Bacterial capsules are antiphagocytic and can reduce the total amount of complement that is deposited on the bacterial surface and the number of pneumococcal cells that are confined in neutrophil extracellular traps.[13]

The innate immune system works in concordance with the adaptive system to encompass a variety of defenses against a broad range of pathogenic mechanisms. The immune system attempts to recognize the pathogen and develop an effective adaptive immune response involving T cells and antibodies to prevent reinfection. These responses are considerably more rapid in onset and evolve swiftly through somatic hypermutations and T cell maturation to effectively neutralize pathogens and also develop memory responses.

Pathogens have evolved a series of mechanisms to avoid immune detection, including local interference with immune processes, antigenic variation, avoidance of inducing immune responses, or inducing ineffective immune responses.[33] The mechanisms by which pathogens display antigenic variation include varying copies

TABLE 124-1 Steps and Molecular Factors for Infectious Microorganisms to Cause Lung Disease

Step	Molecular Factors	Result
Attachment to or entry into the body	Pili, flagella, surface proteins, LPS, specific ligands for receptors on host cells or mucins	Establish organisms in a host
Multiplication	Iron-binding factors; quorum-sensing signals, biofilm matrix	Increase microbial numbers; activate other virulence systems; initiate clinical symptoms
Local spread in the lungs	Capsular polysaccharides, antiphagocytic factors, motility (pili and flagella), toxins	Evade defenses and the natural barriers to spread
Damage to lung tissue, dissemination to bloodstream	Exotoxins (including type III secretion system), LPS, cytotoxins, immunosuppressive factors	Inflict pathology due to the infectious agent, cause systemic evidence of infection (sepsis, septic shock)
Shedding (exit) from the body	None identified	Leave body at site and on a scale that ensures spread to a new host

of an antigenic molecule regulated by an on/off operon, posttranscriptional modification of antigenic genes, and highly variable binding sites. *Neisseria meningitidis* and *K. pneumoniae* use all three of these mechanisms during colonization in the upper respiratory tract as well as in the pathogenesis of their respective diseases. The capsule of pneumococcus and other capsulated organisms prevents antibody as well as complement deposition on its surface.[33] As alluded to earlier, the exotoxin of most organisms is a key virulence factor—but this is also a prime target of the adaptive immune response. Toxin expression in pathogens such as *B. pertussis*[34] and *Corynebacterium diphtheriae*[35] has evolved to escape immune detection by vaccine-induced memory responses and is in part the reason for the resurgence of pertussis particularly in teenagers. CMV causes downregulation of MHC class I and II molecules thereby preventing effective T-cell signaling, and the nucleoprotein of RSV has been shown to inhibit the immunologic synapses between dendritic cells and T cells during infection, resulting in inefficient T cell activation.[33]

The pathogenesis of microbial infections of the lung thus entails complex interactions between the microorganisms and a variety of host defense mechanisms. The general steps and molecular factors involved in the pathogenesis of microbes causing lung infections are summarized in Table 124-1.

UNIQUE ATTRIBUTES

Another mechanism for pneumonic infection can result from conditions that perturb the specific and/or nonspecific mucosal defenses, leading to respiratory infection as a sequela of another pathogenic process. *S. pneumoniae*, *H. influenzae*, and *S. aureus* are the most commonly reported bacteria associated with secondary infections following influenza virus infection. The neuraminidase of influenza virus has been shown to play a synergistic role in pneumococcal pneumonia models by cleaving the sialic acid residues on host glycoconjugates, thereby leading to increased adherence of the bacterium.[36] Denuded epithelial surfaces do provide sites for microbial binding via virulence factors such as SpsA, serine-rich repetitive proteins, and MSCRAMM (microorganism surface components that recognize adhesion matrix molecules) of *S. aureus*.[37] Also, virus-mediated inflammation upregulates certain molecules and apical receptors, including ethylenated glycans (such as GalNacβ1-4Gal) or α5β1 integrin, which promotes binding for organisms like *S. aureus* or *P. aeruginosa*. The exposed collagen and superimposed fibrin deposition stabilizes the adhesion of *S. pneumoniae*, *H. influenzae*, and *S. aureus* to respiratory tissues.[37] Activation of the innate immune response to viral RNA, modeled by polyI:C-mediated stimulation of the TLR3 and RIG-I pathways, which induce type I interferons, can also increase susceptibility of mice to pneumococcal and staphylococcal pneumonia.[38] During the adaptive immune response to influenza in mice, interferon γ can interfere with alveolar macrophage phagocytic function and heighten susceptibility to *S. pneumoniae* pneumonia.[39]

S. aureus infection can aid influenza infection by increasing the infective potential of influenza as the virion is being transduced into host cells within an endosome. The acidic pH within the endosome causes a conformational change to the viral hemagglutinin (HA[0]) allowing cleavage by host proteases into two subunits (HA[1] and HA[2]), thus activating HA, mediating viral-endosome fusion with subsequent opening of the M2 ion channel for viral ribonucleoproteins (vRNP) to be released into the host cell followed by viral RNA. Several strains of *S. aureus* produce proteases that assist in cleavage of influenza HA, allowing for more vRNP to enter host cells with subsequent transcription and viral replication.[40] This aspect contributes to the increased severity of disease caused by co-infection.[41] The stark decrease in staphylococcal pneumonia following measles vaccine programs in sub-Saharan Africa provides a good example of the importance of diminishing initial infections in order to prevent secondary infections. More recently, *S. aureus* pneumonia has been reported after RSV infection and SARS-CoV-2 infection.[42,43]

The human host response to invading pathogens differs across human genotypes, nature of antigenic stimulation, quantity of infectious dose, and route of infection. Some respiratory pathogens, of which measles is the best studied, induce unusual immune effects including its propensity to “reset” the immune systems of infected patients. The acute phase of infection induces immune suppression through a process called immune amnesia by replacing clonal-specific memory cells with new, measles virus [MV]-specific lymphocytes resulting in strong MV-specific immunity but with compromised defenses to many other pathogens.[44,45] MV enters host cells by fusing with the host plasma membranes in a receptor-dependent manner and subsequently infects alveolar macrophages possessing signaling lymphocytic activation molecule (SLAM), circumventing destructive phagocytosis. These infected macrophages then interact and infect memory T cells, memory B cells, and naïve B cells. Clearance of MV requires the abolition of these virally infected lymphocytes via immune-mediated elimination of past memory T cells and B cells, indirectly also creating immune amnesia. Restoration of protective immune memory takes about 2 to 3 years following initial MV infection.[44]

The acute inflammatory response in severe viral pneumonias such as SARS-CoV-2, MERS, and SARS is marked by the activation of proinflammatory cytokines or chemokines leading to the recruitment of inflammatory cells and increased expression of inflammatory, antiviral, and apoptotic genes, which are accompanied by abundant immune cell infiltration and tissue damage.

The magnitude of inflammation associated with an immunologic phenomenon termed the cytokine storm leads to diffuse alveolar damage, hyaline membrane formation, fibrin exudates, and fibrotic healing, which clinically manifests with signs of severe capillary damage, ARDS, and organ dysfunction when these cytokines/chemokines spill over into the circulation. An optimal inflammatory response begins when the pathogen-associated molecular patterns (PAMPs) from the virus are recognized by the pattern recognition receptors (PRRs) of innate immune cells. Specific proinflammatory cytokines are then expressed after the downstream signaling cascades of PRRs are triggered by stimuli. Polymorphisms of PRRs are thought to be the mechanism by which some individuals, but not others, seem relatively resistant to a cytokine storm in the setting of SARS-CoV-2, MERS, and SARS.[46] SARS-CoV-2 causes some degree of lymphopenia with cytotoxic T-cell exhaustion in association with evoking a cytokine storm in susceptible individuals.[46]

SPECIAL CONSIDERATIONS

Chronic bacterial lung infections can be caused by a variety of pathogens, many of which occur in persons with underlying lung disease. Patients with chronic obstructive pulmonary disease (COPD) are particularly susceptible to chronic infection with nontypeable *H. influenzae*. Beyond the propensity of *H. influenzae* to bind to respiratory mucins,[16] the molecular basis for infection and disease are mostly unclear. Interestingly, co-colonization experiments with *H. influenzae* and *S. pneumoniae* in mice have found that *H. influenzae* predominates due to *H. influenzae*–induced complement-dependent phagocytic killing of *S. pneumoniae*.[47]

Among patients with cystic fibrosis (CF), 80% to 90% will become chronically infected with *P. aeruginosa* (Chapter 48). This pathogen is currently the major factor limiting their life expectancy. Of note, while use of newer technologies that identify the complex mixtures of microbial DNA in samples of human tissues and secretions has greatly expanded our insights and understandings into the microbial communities or microbiomes present in the GI and vaginal tracts, skin, and oropharynx, the role they play in chronic respiratory infections is still under assessment. In CF, increasing concurrence with the concept of a community of microbes being associated with disease has to be placed in the context of findings that, when examining tissues from autopsies or lung transplants, only traditional CF pathogens such as *P. aeruginosa* are found by either culture or DNA analysis. In contrast, microbiome community DNA is found in oropharyngeal swabs and expectorated sputum that must come through the oropharynx in order to be collected,[48] likely confounding the conclusion that these organisms are truly present in the lung and contributing to disease pathogenesis.

Thus, *P. aeruginosa* remains the major infectious entity associated with pulmonary decline in CF, and a large research effort has focused on understanding how this pathogen infects the vast majority of patients with a genetic defect that does not appear related to chronic bacterial lung infection. In patients with CF, mutations are found in the CF transmembrane conductance regulator (CFTR) gene, which codes for a large protein that regulates chloride ion secretions directly and also appears to affect the flow of glutathione and bicarbonate. Some 70% of persons carry at least one mutant CFTR allele that lacks the codon for the phenylalanine at position 508 (ΔF508 mutation), making one-half of affected persons (∼49%) homozygous for this mutation. The lack of phenylalanine at position 508 leads to an inability of the mature protein to get into the cell membrane.

The relationship of mutant CFTR and hypersusceptibility to chronic *P. aeruginosa* infection is undergoing intensive study. Pier et al. have proposed that clearance of *P. aeruginosa* from the lung following inhalation of bacteria is critically dependent on CFTR-controlled internalization of the bacterium by lung epithelial cells followed by rapid activation of innate immunity involving NF-κB nuclear translocation and production of inflammatory cytokines such as IL-6, IL-8, and CXCL1.[48,49] The combined effects of epithelial cell internalization and shedding, along with rapid activation of innate immunity that most likely brings in neutrophils to phagocytose and eliminate additional extracellular bacteria, can lead to efficient microbial clearance. Resolution of this response via apoptosis has also been shown to be important in the CFTR-dependent response of the lung to *P. aeruginosa*. The CFTR protein has been identified as the actual cellular receptor for clearance of *P. aeruginosa* from the lung. In a neonatal mouse model of clearance of *P. aeruginosa* from the lungs after nasal inoculation of bacteria, it was found that blocking of CFTR-mediated epithelial cell ingestion of *P. aeruginosa* led to higher bacterial burdens in the lung. Similarly, in transgenic CF mice there is reduced epithelial cell uptake of *P. aeruginosa* and increased overall bacterial burdens in the lung. Of note, there appeared to be little to no binding of bacteria to tracheal epithelial cells in the infected CF mice, whereas extensive binding, ingestion, and shedding of *P. aeruginosa* by epithelial cells could be seen in tracheas of infected wild-type mice. Thus, in vivo, *P. aeruginosa* binding to CF epithelial cells is not observed, a situation completely consistent with results from histopathologic examination of lungs taken at transplant or autopsy from CF patients, where *P. aeruginosa* also is not seen binding to the epithelium but rather encased in mucus plugs within the airways. Overall, the initial establishment of *P. aeruginosa* infections in the lungs of CF patients can be directly attributable to the lack of functional CFTR in cell membranes to bind to this microbe and initiate appropriate innate immune responses, which overall prevents efficient bacterial clearance from the lung. Additional factors in the CF lung, such as reduced airway surface pH, as noted in the recently developed CF pig model,[50] may also play a role in impaired innate defenses against *P. aeruginosa* and other bacteria.

The pathogenic mechanisms leading to chronic *P. aeruginosa* lung infections in CF patients are more extensive. After avoiding initial clearance, the bacteria adhere to mucins and become embedded in mucus plugs within the airways[51] and eventually undergo a phenotypic conversion wherein they both lose their ability to produce the long O-polysaccharide side chains that are usually on the LPS and acquire the ability to elaborate copious quantities of a bacterial exopolysaccharide called alginate. The hypermutable phenotype seen in *P. aeruginosa* strains from CF patients likely speeds this adaptation.[52] Alginate is unable to provoke a protective antibody response in the host[53] and encases the bacteria in microcolonies within a hypoxic microenvironment in the lung.[54] Within this protective coating, phagocytes such as neutrophils are unable to ingest and kill the microorganisms. This leads to a vicious cycle of additional but ineffective inflammation and bacterial growth, the result of which is tissue destruction subsequent to the chronic inflammatory process. Alterations in the lipid A structure of the *P. aeruginosa* LPS in strains isolated from CF patients appear to confer resistance to antimicrobial peptides and a hyperinflammatory response.[55] For most of the patient's life, *P. aeruginosa* infection appears to remain confined to endobronchial surfaces, which become plugged with mucus while the airway tissues are being destroyed, although recently reported histopathologic results from lungs of CF patients who died in the 1970s also showed extensive alveolar involvement, prior to more modern medical management with aggressive anti-*Pseudomonas* antibiotic therapy.[56] The finding of quorum-sensing signals in the CF lung suggests that *P. aeruginosa* may exist as a biofilm (defined as a structured community of bacteria encased in a self-produced matrix), which likely contributes to the recalcitrance of this infection to antibiotics,[57] as does the recently described ability of *P. aeruginosa* to produce the gases hydrogen sulfide and nitric oxide in order to resist the oxidative stress induced by antibiotics.[58,59] Thus, the pathogenesis of chronic *P. aeruginosa* infection in CF involves at least two components: an initial phase of hypersusceptibility to infection that is predicated on an inability of CF patients to kill or clear inhaled *P. aeruginosa* cells, and a subsequent phase directly related to the bacterium's ability to elaborate alginate, which allows the organism to resist host defenses while continuing to provoke inflammation that damages lung tissues.

From this example of chronic lung infection, we garner some important insights into mechanisms whereby bacterial pathogens cause lung infections. Many of the principles apply to other types of pathogenic microbes that follow the basic scenario of entry, attachment, multiplication and survival, elicitation of inflammation, and ultimately tissue damage and compromise of respiratory function. Although each of these steps can often be characterized at a highly specific molecular level, usually using isolated factors such as toxins to elicit clinical symptoms of disease, the overall pathogenesis of disease requires that elaboration of molecular factors of pathogenesis be coordinated and that each step in the process occur under the proper circumstances and at the right time. Research in identifying and understanding the microbe's genetic and molecular factors that control and coordinate pathogenesis is still in its infancy. Presumably, greater understanding of particular factors and the interactions among both the factors and host tissues will lead to development of better vaccines and other therapies that will minimize the occurrence of microbial infections in the lung.

CHAPTER 125

Principles of Antibiotic Use and the Selection of Empiric Therapy for Pneumonia

Girish B. Nair
Michael S. Niederman

INTRODUCTION

Antibiotics are the foundation of therapy for respiratory tract infections. The approach to use varies with the type of pneumonia, age of the affected patient, presence of various comorbid illnesses, risk factors for infection by specific pathogens, and severity of the acute illness. For most patients, initial therapy is empiric, aimed at a broad spectrum of potential pathogens. Once culture data become available, therapy can be pathogen-specific making it possible to de-escalate to fewer drugs with a narrower antimicrobial spectrum.[1] In some cases, initial empiric therapy must be continued because no etiologic pathogen is identified.

The transformation of modern medicine over the last century can be attributed in part to the discovery and development of antibiotics. However, with widespread use of antibiotics, antimicrobial resistance in bacterial pathogens has become rampant, and once easily treatable conditions, such as pneumococcal pneumonia, are becoming deadly again.[2] The Presidential Executive Order 13676 for Combating Antibiotic-Resistant Bacteria (CARB) released in 2014 recognizes the importance of curbing antimicrobial resistance and sets forward a set of principles to help tackle this emerging issue.[1]

When a pathogen is defined, the term "appropriate" refers to the use of at least one antimicrobial agent that is active in vitro against the etiologic pathogen. The term "adequate" includes not only appropriate therapy, but also the use of that agent in the correct dose, via the right route, given in a timely fashion, and with penetration to the site of infection. Timely and appropriate antibiotic therapy can improve survival in patients with community-acquired pneumonia (CAP) and nosocomial pneumonia or hospital-acquired pneumonia (HAP), and the benefits are most evident in patients who are not otherwise terminally ill.[3,4] Ventilator-associated pneumonia (VAP) is nosocomial pneumonia that develops after at least 48 h of preceding mechanical ventilation, and thus some ventilated HAP patients may not have VAP, since they do not satisfy this definition of prolonged preceding mechanical ventilation.

In the setting of CAP, effective initial antibiotic therapy is associated with a marked improvement in survival, compared with ineffective therapy, particularly in patients with severe illness.[3,5] In several studies, identification of the pathogens causing severe CAP did not lead to an improved survival rate, while the use of a broad-spectrum, empiric regimen directed at likely pathogens reduced mortality. Further, patients with CAP have reduced mortality if initial antibiotic therapy is provided within 4 h of arrival to the hospital. In the treatment of VAP, data show that appropriate therapy should be given as soon as the infection is clinically identified, and lower respiratory tract samples have been collected for culture. Delay of even 24 h in starting therapy is an important mortality risk factor in VAP.[4] In general, with severe illness, those receiving antibiotics earlier in their course have a lower mortality than those receiving delayed therapy, with the risk of death rising 7% to 8% for each hour of delay of therapy during the first 6 h of septic shock and hypotension.[6]

Even with the use of correct agents, not all patients recover. The fact that some HAP patients die in spite of microbiologically appropriate therapy is a reflection of the degree of antibiotic efficacy, as well as a reflection of host response capability (which may in part have a genetic determinant). Antibiotic effectiveness and clinical success are a complex system-level process, sensitive to environmental factors after drug administration, such as protein binding, intrapulmonary penetration, drug distribution, pharmacokinetic and pharmacodynamic properties, and host characteristics, such as the presence of comorbid conditions, immune related lung damage, and nonpulmonary complications.[7] In some HAP patients, death is the result of the serious underlying illness; the percentage of deaths that occur because of infection, termed "attributable mortality" of HAP, has been estimated to be as high as 50% to 60%, but timely use of appropriate antimicrobial therapy can reduce this attributable mortality to 20% or lower.[8,9]

The American Thoracic Society and Infectious Diseases Society of America (ATS/IDSA) have updated both CAP and HAP/VAP guidelines recently.[3,4] These guidelines emphasize the importance of timely, appropriate, and adequate antibiotic coverage to decrease mortality and avoid drug resistance. In the case of CAP, the emergence of penicillin-resistant pneumococcus, community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA), and epidemic viral illness (influenza, SARS, and SARS Coronavirus-2) may affect the selection of initial therapy. The "PES" pathogens (*Pseudomonas aeruginosa*, Enterobacteriaceae that are extended-spectrum β-lactamase–positive, and methicillin-resistant *Staphylococcus aureus*) account for up to 6% of hospitalized CAP and require specific therapy different from standard CAP therapy.[10] In the setting of HAP, each hospital, and each ICU within that hospital, has unique flora and antimicrobial susceptibility patterns; knowledge of such patterns is essential for selection of the optimal agents.

The majority of data establishing "standard" antibiotic doses are derived from studies in healthy volunteers or non–critically ill hospitalized patients, which have been extrapolated to a wide range of patients, including the elderly, the obese, and the critically ill, with differing clearances of these agents. Critically ill patients may manifest significantly altered end-organ function, whereas those with sepsis may have a hyperdynamic circulation and augmented renal clearance (ARC), necessitating higher than normal doses of antibiotics to achieve effective serum and intrapulmonary concentrations. In these patients, as well as in obese individuals who have an altered volume of distribution (Vd) of some drugs, subtherapeutic concentrations may result in treatment failure or in selection of antimicrobial-resistant organisms.[11] Several novel antibiotics with different mechanisms of action have recently been approved and may offer broad-spectrum coverage—particularly for those who are intolerant of, or not responding to, standard treatment, including those who harbor drug-resistant pathogens.[12]

In this chapter, the principles underlying antibiotic use are examined, followed by a discussion of the commonly used antibiotics for respiratory tract infections, the principles of empiric therapy of both CAP and HAP, and an overview of newer antibiotic choices for treatment of pneumonia. Further, pharmacokinetic and pharmacodynamic considerations are a theoretical way to optimize the delivery of antibiotics. To preserve antibiotics for future use, it is necessary to understand mechanisms of antibiotic resistance and to practice antimicrobial stewardship by focusing on proper antibiotic dosing, de-escalation therapy, and the development of local protocols for antibiotic choice, but not necessarily by restricting access to potentially effective broad-spectrum agents for seriously ill patients.

PRINCIPLES OF ANTIBIOTIC USE

Antibiotics interfere with the growth of bacteria using various mechanisms, including undermining the integrity of their cell wall and interfering with bacterial protein synthesis or common metabolic pathways. The mechanism of activity can be used to define whether an agent is bacteriostatic or bactericidal, terms discussed in "Mechanism of Action," below.

MECHANISM OF ACTION

Bactericidal antibiotics kill bacteria, generally by inhibiting cell-wall synthesis or by interrupting a key metabolic function of the organism. Agents of this type include the penicillins, cephalosporins, aminoglycosides, fluoroquinolones, vancomycin, daptomycin, colistin/polymyxin, rifampin, and metronidazole. *Bacteriostatic agents* are antibiotics that inhibit bacterial growth but generally do not interfere with cell-wall synthesis and rely on host defenses to eliminate microbes. Agents of this type include the macrolides, tetracyclines, sulfa drugs, chloramphenicol, linezolid, and clindamycin.

The terms *bactericidal* and *bacteriostatic* are broad categorizations and may not apply for a given agent relative to all organisms, with certain antimicrobials being bactericidal for one bacterial pathogen but bacteriostatic to another.[13] The use of a specific agent is dictated by the susceptibility of the causative organism(s) in a given anatomic location to individual antibiotics. However, a meta-analysis evaluating categorization of antibiotics did not show differences in clinical cure rate or mortality rate between patients treated with bacteriostatic or bactericidal antibiotics.[14] When neutropenia or immune compromise are present or if there is accompanying endocarditis or meningitis, the use of bactericidal agents is preferred. Thus, for most patients with pneumonia, it is not essential to choose a bactericidal agent. One additional consideration is that certain organisms such as *S. aureus* can produce toxins, and the optimal agent must be able to kill the bacteria and also to inhibit the production of disease-mediating toxins. Agents that inhibit bacterial toxin production include clindamycin, rifampin, and linezolid.

The *minimum inhibitory concentration (MIC)* is the minimum antibiotic concentration necessary to inhibit the growth of 90% of a standard sized inoculum, leading to no visible growth in a broth culture. The MIC is used to define the sensitivity of a pathogen to a specific antibiotic, under the assumption that the concentration required for killing (the MIC) can be reached in the serum in vivo. This term must be interpreted cautiously in the treatment of pneumonia, because the clinician must consider the MIC data in light of the penetration of an agent into lung tissues, with some agents achieving higher than serum levels at respiratory sites of infection and others reaching lower levels.[15,16]

The *minimum bactericidal concentration (MBC)* is the minimum concentration needed to cause a 3-logarithmic decrease (99.9% killing) in the size of the standard inoculum, and generally all pathogenic bacteria are killed at this concentration.

The *mutation prevention concentration (MPC)* is the lowest concentration of an antimicrobial agent that prevents bacterial colony formation from a culture containing greater than 1010 bacteria.[15] At lower than MPC concentrations, spontaneous mutants can persist and be enriched among the organisms that remain during therapy. The concept has been most carefully studied with the pneumococcus and fluoroquinolones. In general, the MPC is higher than the MIC, implying that it is possible to use an antimicrobial to successfully treat a clinical infection but with inadequate levels to eradicate the bacteria. These remaining organisms may provide a basis for the emergence of antimicrobial-resistant bacteria.

IMPORTANT PHARMACOKINETIC–PHARMACODYNAMIC VARIABLES

Pharmacokinetics refers to the absorption, distribution, and elimination of a drug in the body, which can be used to describe the concentration of a drug in the serum. *Pharmacodynamics* refers to the physiologic and biochemical effects of a drug on the body or any organisms within the body, the mechanisms of action, and the relationship between a drug's concentration and effect. Bacterial killing is affected by the way in which an antibiotic reaches the site of infection considering the frequency of administration and dose administered, thus defining a close relationship between pharmacokinetic and pharmacodynamic.[15,16]

There are three types of bactericidal antibiotics. First, are those that kill in relation to the duration in which the non-protein-bound free concentration of the agent stays above the MIC of the target organism, $f\mathrm{T} > \mathrm{MIC}$ *(time-dependent killing)*.[13] Examples include the β-lactams, carbapenems, aztreonam, macrolides, and linezolid. For maximal efficacy, β-lactam concentrations should be maintained at four times the MIC, for approximately 40% to 70% of the dosing interval, depending on the agent being employed.[16] Generally, carbapenems should exceed the MIC for at least 40% of the dosing interval, penicillins for 40% to 50%, and cephalosporins for 60% to 70% of the dosing interval. Second are agents that kill in relation to how high the peak concentration is, relative to the MIC, defined by the C_{max}:MIC ratio *(concentration-dependent killing)*.[16] Examples include the aminoglycosides and fluoroquinolones, as well as the ketolides. Finally, agents like the glycopeptides (vancomycin), daptomycin, linezolid, colistin, tigecycline, and the fluoroquinolones are bactericidal by *both concentration and time-dependent killing mechanisms*, and have efficacy defined by the area under the concentration–time curve divided by the MIC (AUC: MIC ratio, or AUIC).[17]

To optimize time-dependent killing, dosing should be chosen to achieve the maximal time above the MIC of the target organism; this can be done with continuous or prolonged (over 3–4 h) infusions. The rate of killing is saturated once the antibiotic concentration exceeds four times the MIC of the target organism. In spite of these considerations, for many organisms, the concentration of a carbapenem only needs to be above the MIC for 40% of the dosing interval.[15]

The target AUIC for Gram-negative bacteria is 125 or greater, whereas for most antibiotics that treat the pneumococcus, the target value is at least 30. Some studies have shown that aiming for C_{max}/MIC target of 12 for fluoroquinolones against pneumococcus is optimal. Appropriate use of these agents would entail infrequent administration but with high doses, which is the underlying principle behind the once-daily administration of aminoglycosides.

The *post-antibiotic effect (PAE)* maintains the efficacy of the antibiotic after the serum (or lung) concentrations have fallen below the MIC of the target organism. Thus, with once-daily aminoglycoside dosing regimens, the patient achieves a high peak concentration (maximal killing), and a low trough concentration (minimal nephrotoxicity) with the PAE achieving continued antimicrobial effects. While most agents exhibit a PAE against Gram-positive organisms, prolonged PAEs against Gram-negative bacilli are achieved by the aminoglycosides and fluoroquinolones.[15,16] For pneumococcus, a PAE exists for the macrolides/azalides, clindamycin, vancomycin, quinupristin/dalfopristin, tetracyclines, and the oxazolidinones (such as linezolid). Most of the agents that kill in a concentration-dependent fashion have a prolonged PAE. Agents with little or no PAE against Gram-negatives are generally also agents that kill in a time-dependent fashion and are administered several times daily. The β-lactams (including the penicillins, cephalosporins, and monobactams) generally have little or no PAE against Gram-negatives; one notable exception is imipenem, which has a modest

PAE against *Pseudomonas aeruginosa*. In clinical practice, the use of once-daily aminoglycoside dosing has had variable benefits in both efficacy and toxicity, but the advent of this type of dosing regimen follows from an understanding of pharmacodynamic principles. *Post-antibiotic leukocyte enhancement (PALE)* refers to the ability of functioning leukocytes to kill organisms in the post-antibiotic phase of growth. Thus, when the patient has functioning neutrophils, the PAE of some agents is extended by their PALE.

Some investigators have suggested that antibiotics should be selected based on whether they stimulate *inflammation* and cytokine production in response to the presence of the bacterial cell-wall lysis products.[13] Certain antibiotics liberate bacterial cell-wall products that interact with cytokine-producing cells, stimulating the production of high levels of cytokines such as tumor necrosis factor. In theory, this could lead to the development or the worsening of sepsis syndrome. This may be a consideration in patients with *Pneumocystis jiroveci* pneumonia or pneumococcal meningitis who may benefit from the use of corticosteroids with antimicrobial therapy in these infections. In general, the clinical role of cytokine release is uncertain, but bactericidal antibiotics tend to produce a greater host inflammatory response than bacteriostatic agents. Antibiotics that are cell wall–active, and that kill slowly, have been associated with the greatest cytokine release.

As noted previously, the use of antibiotics that inhibit protein synthesis (linezolid, clindamycin) may have an advantage in toxin-mediated illnesses, such as those caused by certain strains of *S. aureus*, when compared with cell wall–active bactericidal antibiotics.[18]

FACTORS AFFECTING ANTIBIOTIC CONCENTRATIONS

Alterations in lung penetration, protein binding, and changes in drug volume of distribution (Vd) and clearance (Cl) can significantly influence antibiotic concentrations achieved at a site of infection and, therefore, the probability of microbiologic success.[11] Furthermore, in critically ill patients, drug elimination is likely to be markedly different from healthy volunteers, and thus it is challenging to define optimal dosing in these patients.[11,19,20] In critically ill patients, concentrations may be higher or lower than in other patients. For example, with sepsis, and hyperdynamic cardiac function, patients may have augmented renal clearance (ARC), defined as a creatinine clearance >130 mL/min; the serum concentrations may be lower than expected, with normal dosing. In those with volume overload, Vd may increase and lead to lower serum drug levels, while altered renal and hepatic function can reduce drug clearance and cause higher than normal levels.[21] Organ support, such as renal replacement and extracorporeal membrane oxygenation (ECMO), may raise or reduce serum concentrations, depending on the agent being used.

Beyond the immediate threat of treatment failure, subtherapeutic antibiotic concentrations are a risk factor for the selection of drug-resistant organisms.[22] In critically ill patients, it is common to underdose antibiotics, and in one study it was common for patients not to achieve adequate time of β-lactam therapy above the target MIC, with at least 20% not achieving even a conservative target of having serum concentrations exceed the MIC of the target pathogen for at least 50% of the dosing interval.[23] Tigecycline resistance was identified within months of the commercial release of this antibiotic, and this may have been related to suboptimal concentrations at the site of infection.[24] In this respect, accurately identifying patients at risk of suboptimal drug exposure for a given causative pathogen remains a difficult clinical problem. Those most at risk for underdosing have a history of recent surgery, reduced creatinine clearance, and use of β-lactams by intermittent infusion. While therapeutic drug monitoring (TDM) provides the most robust means of identifying subtherapeutic concentrations, its availability for all classes of antibiotic is largely limited to specialized centers.[25] In addition, changing organ function during the course of critical illness will affect antibiotic PK parameters, necessitating a regular review of dosing requirements. TDM has shown its greatest value with aminoglycosides, voriconazole, and ribavirin, but a consensus statement suggested that if available, TDM should also be done for β-lactams, vancomycin, and linezolid.[26] Currently, empiric dosing can be done by computer-based nomograms that use input from population pharmacokinetics and individual patient factors.[27]

PENETRATION INTO THE LUNG

A key requirement for the successful treatment of pneumonia is the achievement of therapeutic drug concentrations at the site of infection; in pneumonia, the targets are the lung parenchyma and alveoli (Table 125-1).[28] The drug concentration within the epithelial lining fluid (ELF) has been the most commonly used surrogate in pneumonia therapy. Research over a number of years has established that there is wide variability both within and between antibiotic classes in terms of ELF penetration.[16,29] The physiochemical properties that govern drug movement across biologic membranes include the degree of ionization, fat solubility, molecular weight, and protein binding. Despite accounting for such characteristics, many of the differences between antibiotics in ELF to plasma concentration ratios (C_{ELF}:C_{Plasma}) remain poorly understood.[29] Sputum and bronchial concentrations may be the most relevant measurements for bronchial infections, whereas the concentrations in lung parenchyma, ELF, and cells such as macrophages and neutrophils may be more important for pneumonia. The localization of the pathogen also may be important; intracellular organisms such as *Legionella pneumophila* and *Chlamydophila pneumoniae* may be best eradicated by agents that achieve high intracellular concentrations in macrophages.

Macrolides have good penetration into ELF (e.g., C_{ELF}:$C_{Plasma} > 10$ for azithromycin),[29] whereas β-lactams have varying penetration ratios[30] without a predictable pattern. Vancomycin demonstrates limited lung penetration (C_{ELF}:$C_{Plasma} < 1$),[31] while both linezolid and fluoroquinolones are reported to have ELF concentrations equivalent to or greater than those in plasma (C_{ELF}:$C_{Plasma} \geq 1$).[32,33] Specific

TABLE 125-1 Penetration of Antibiotics into Respiratory Secretions

Good Penetration: Lipid Soluble, Concentration Not Inflammation Dependent
Quinolones
New macrolides: azithromycin, clarithromycin, solithromycin
Ketolides (telithromycin)
Tetracyclines
Doxycycline
Tigecycline
Omadacycline
Clindamycin
Trimethoprim-sulfamethoxazole
Poor Penetration: Relatively Lipid Insoluble, Inflammation Dependent for Concentration in the Lung
Aminoglycosides
β-lactams
Penicillins
Cephalosporins
Monobactams
Carbapenems

data from critically ill subgroups are generally limited, and in those where results have been reported, significant interpatient variability has been noted.[34] Another glycopeptide, daptomycin is inactivated by pulmonary surfactant and should not be used for treatment of lower respiratory tract infections but is used to treat bacteremia due to susceptible pathogens.

The quinolones kill in a concentration-dependent fashion allowing optimal antibacterial activity with infrequent dosing and high peak concentrations and high ratios of AUC/MIC or C_{max}/MIC. In addition, because quinolones have a post-antibiotic effect against both Gram-positive and Gram-negative organisms, killing is maintained after local concentrations fall below the MIC of the target organism. These properties allow the fluoroquinolones to be infrequently dosed, often once daily, particularly given the longer half-life of the newer compounds. The factor limiting once-daily dosing for all quinolones is the toxicity associated with higher doses of some agents such as ciprofloxacin, with neurotoxicity and possible seizures.

Two features of quinolones that make them well suited to respiratory infections are good oral bioavailability and excellent penetration into respiratory secretions and inflammatory cells within the lung, achieving local concentrations that often exceed serum levels; similar serum and tissue levels can be reached with oral or intravenous administration. Given good lung penetration, the quinolones may be clinically more effective than predicted by MIC values and may be better than other agents in prolonging the "disease-free" interval between exacerbations of COPD, a finding that has been demonstrated for moxifloxacin.[35] High bioavailability allows some "borderline" patients (such as nursing home patients) with pneumonia to be managed with outpatient oral therapy and maintain high therapeutic levels in the serum. In addition, these agents permit an easy transition from intravenous to oral therapy of inpatients with pneumonia.

The local concentration of an antibiotic must be considered in light of the activity of the agent at the site of infection, as well as the presence of bacterial resistance mechanisms. For example, antibiotics can be inactivated by certain local conditions. Aminoglycosides have reduced activity in acidic pH, which may be present in infected lung tissues. In addition, some bacteria develop resistance by producing destructive enzymes (such as β-lactamases), by altering the permeability of the outer cell wall, by changing the target site of antimicrobial action, or by pumping (efflux) of the antimicrobial from the interior of the cell. In these conditions a high local concentration of antimicrobial may help to offset bacterial resistance mechanisms.

The concentration of an antibiotic in lung parenchyma depends on the penetration through the walls of the bronchial capillaries, which have a fenestrated endothelium. Antibiotics penetrate in proportion to their molecular size and protein binding with small molecules that are not highly protein bound passing readily into the lung parenchyma. When inflammation is present, penetration is increased. Antibiotics reaching the ELF must pass through the pulmonary vascular bed with a nonfenestrated endothelium. This presents an advantage for lipophilic agents, which are generally not inflammation-dependent.

Lipophilic agents include chloramphenicol, the macrolides (including the azalides and ketolides), linezolid, clindamycin, the tetracyclines, the quinolones, and trimethoprim-sulfamethoxazole (TMP-SMX). Agents that are poorly lipid soluble are inflammation-dependent for entry into the ELF; these include the penicillins, cephalosporins, aminoglycosides, vancomycin, carbapenems, and monobactams.

Active transport can facilitate antibiotic entry into lung tissue and phagocytes. Agents that are concentrated in phagocytes in this manner include the macrolides, clindamycin, and the fluoroquinolones. Antibiotics, such as the β-lactams, that are not concentrated in phagocytes by active transport remain in the extracellular space, which constitutes 40% of the weight of bronchial tissue; thus, penicillins achieve only about 40% of the serum level in lung tissue.

Drugs that penetrate well into the sputum or bronchial tissue include the quinolones, the newer macrolides and azalides (azithromycin and clarithromycin), the ketolides (telithromycin), the tetracyclines, clindamycin, and TMP-SMX. On the other hand, the aminoglycosides, vancomycin, and to some extent the β-lactams, penetrate less well into these sites. With the use of once-daily aminoglycoside dosing, high peak serum concentrations can be achieved, but the alveolar lining fluid concentration in patients with pneumonia is only 32% of the serum level over the first 2 h; the two sites have more similar concentrations later in the dosing interval.[36] Since aminoglycosides require high peak concentrations for optimal killing, their poor penetration with systemic administration often impacts efficacy, suggesting a potential role for delivery by the aerosol route.

VOLUME OF DISTRIBUTION

The Vd describes the relationship between the dose administered to the concentration of the drug that is measured in blood or plasma. Values exceeding 3 L imply a distribution outside the plasma. Hydrophilic drugs that are poorly lipid soluble diffuse freely into interstitial fluid but do not penetrate cells. Thus, only the free, non-protein-bound drug can be distributed outside the plasma. Aminoglycosides and β-lactams are hydrophilic and will distribute into the extracellular space (~0.6 L/kg).[37] Lipophilic agents such as the macrolides and quinolones are extensively distributed in body tissues, and serum levels underestimate the effect at the site of infection. This observation explains the efficacy of azithromycin, which achieves relatively low serum levels with high intracellular concentrations, yet can treat pneumonia.

Vd is also affected by obesity. Dosing based on ideal body weight may lead to underdosing in general, while for hydrophilic antibiotics, dosing based on total body weight may result in excessive drug levels. In critical illness, the Vd of many agents can differ from that in healthy subjects, primarily as a reflection of changes in microvascular function. Volume resuscitation, a ubiquitous intervention in critical illness, may also increase Vd for hydrophilic agents in the face of increased capillary permeability and interstitial edema.[38,39] Sánchez et al.[40] described the hemodynamic changes observed after fluid resuscitation for septic shock, showing that antibiotics such as the β-lactams, aminoglycosides, and glycopeptides "go where the water goes," meaning that in critical illness, these drugs will be preferentially "dragged" into the interstitial space by extravascular movement of free fluid. The Vd of such drugs is much higher than in the absence of "leaky" capillaries. This effect is associated with decreased serum concentrations for any given dose; thus a larger dose is required to compensate for the increased Vd. As patients improve, fluid redistribution from tissues into the vascular space occurs, resulting in a significant decrease in the Vd. Thus, for drugs that distribute into extravascular interstitial fluid, an initial loading dose[41] is required to adequately "fill" these compartments and the Vd will change in parallel with each patient's physiology. This may explain why higher doses of vancomycin were needed to reach target serum concentrations in ICU patients in whom standard "ward" doses are likely to be inadequate. A larger Vd is also well described for β-lactams.[42]

PROTEIN BINDING

Many antibiotics demonstrate plasma protein binding, to either albumin or alpha-1-acid glycoprotein (AAG),[37] which can be disturbed in critical illness with many patients manifesting hypoalbuminemia.[43] The free fraction of the drug is eliminated with low plasma protein concentrations, resulting in an increase in Vd and clearance (CL) for highly protein-bound agents such as flucloxacillin, ertapenem, ceftriaxone, and teicoplanin.[43] Measuring the free drug concentration can be technically difficult; thus most published research has focused on total serum levels without correction for protein binding based on data from healthy volunteers.

DRUG CLEARANCE

Drug clearance represents the volume of plasma cleared of a specific pharmaceutical per unit time, and it can involve organ-independent enzymatic degradation, hepatic metabolism, or renal elimination of the parent compound or metabolites. During critical illness many aspects of these elimination pathways are disturbed. There are changes in major organ blood flow, saturation of enzyme systems, or complex drug–drug interactions.[37] Few data are available that describe the impact of changes in hepatic function on antibiotic pharmacokinetics and pharmacodynamics.

For many antibiotics (such as the aminoglycosides, β-lactams, and glycopeptides), renal drug clearance is directly proportional to creatinine clearance (CrCl).[37] With the administration of large volumes of fluid and the use of vasoactive agents in critically ill patients with sepsis, trauma, or burns, and in neurosurgery patients, there is often an increased cardiac output and organ perfusion with enhanced delivery of solute to drug-eliminating organs leading to the phenomenon of augmented renal clearance (ARC).[44] With ARC, serum creatinine concentrations are almost always within the "normal range," while measured creatinine clearance is elevated, even as high as 200% of normal. This may lead to suboptimal trough β-lactam concentrations in critical illness, thereby impacting the likelihood of achieving the necessary amount of time that the drug reaches an adequate concentration above the MIC targets.[44] ARC is mostly seen in male patients age 50 to 55 years with a higher mean diastolic BP and having fewer comorbidities, lower Sequential Organ Failure Assessment scores, and lower Acute Physiology and Chronic Health Evaluation (APACHE) II scores. In such patients the use of an isolated serum creatinine concentration to extrapolate GFR is not possible; dosing derived from noncritically ill patient populations may fail to account for ARC. In this setting, a timed urinary CrCl provides a simple, cheap, and repeatable estimate of renal drug elimination[45] and affords an alternate means of identifying such patients. From an antibacterial prescribing perspective, ARC will lead to an increased rate of drug elimination and may necessitate more frequent intermittent doses or administration by continuous or extended infusion.[46]

A paucity of data to guide dose selection is also present when patients receive extracorporeal renal replacement therapy (RRT, such as continuous veno–venous hemofiltration, hemodialysis, and hemodiafiltration). In such instances, native renal drug elimination is limited (although not completely absent), whereas nonrenal mechanisms may assume a greater role in total body clearance. As a consequence, highly variable antibiotic concentrations have been observed in patients receiving RRT.[47] The variety of RRT modalities available further complicates such determinations due to variations in the parameters employed (including blood flow rates, effluent flow rates, and membrane pore size) and the unique physiochemical characteristics of each drug.

Drugs that are hydrophilic have good clearance with dialysis. Although not similar to those with normal renal function, comparatively smaller molecules such as β-lactam and aminoglycosides are cleared with dialysis, whereas large molecules such as vancomycin are not cleared with dialysis.[11] Not surprisingly, optimal dosing strategies in RRT remain largely uncertain. Lately, extracorporeal membrane oxygenation (ECMO) has resulted in increased Vd with decreased CL, but limited data are available for pharmacokinetic and pharmacodynamic of antibiotics in these patients.[11]

The role of continuous infusion dosing (CD) for time-dependent antibiotics has been extensively studied as a means to optimize *concentration of drug as function of time over MIC*, with numerous studies suggesting an improved ability to achieve the required pharmacokinetic and pharmacodynamic targets,[48,49] particularly with more virulent bacteria. In the BLISS trial, an open-label, randomized study including 140 severe sepsis patients, CD was associated with higher clinical cure rates compared with intermittent dosing (ID) in those patients not receiving RRT with no overall difference in mortality.[50] Dulhunty et al.,[51] using three commonly prescribed β-lactams, showed that CD was associated with a significantly improved ability to achieve optimal pharmacokinetic–pharmacodynamic targets along with higher clinical cure rates; however, no difference was identified in ICU-free days or hospital survival. In a recent meta-analysis of 3 randomized controlled studies, including 632 patients with severe sepsis, Roberts et al. reported a significantly better in-hospital mortality (19.6% vs. 26.3%; $p = 0.045$) and clinical cure (55.4% vs. 46.3%; $p = 0.021$) with CD compared to ID.[52] Other factors such as ARC could pose unique challenges on drug dosing and reinforce the need to further investigate optimal dosing strategies in those with critical illness.[19]

ANTIMICROBIALS USED IN THE THERAPY OF RESPIRATORY TRACT INFECTIONS

A variety of classes of antibiotics are used in the treatment of respiratory tract infections. Each is discussed below.

■ Macrolides (Including Azalides)

Macrolides are bacteriostatic agents that bind to the 50S ribosomal subunit of the target bacteria and inhibit RNA-dependent protein synthesis. They have good activity against pneumococci as well as "atypical" pathogens (*C. pneumoniae*, *Mycoplasma pneumoniae*, *Legionella*). Older macrolides including erythromycin are not active against *Haemophilus influenzae* and have poor intestinal tolerance, so prolonged therapy is difficult. The newer agents in this class include azithromycin (also referred to as an azalide), clarithromycin, and solithromycin. Among the macrolides, azithromycin is more active than clarithomycin against *H. influenzae* (including beta-lactamase-producing strains), *M. catarrhalis*, and *M. pneumoniae*, whereas clarithromycin has shown to be more active against *Legionella*, *C. pneumoniae* and *Streptococcus pneumoniae*.

Both azithromycin and clarithromycin have better intestinal tolerance than erythromycin and penetrate well into sputum, lung tissue, and phagocytes. Clarithromycin, which has an active 14-hydroxy metabolite that is antibacterial, is administered twice a day orally at a 500-mg dose for 7 to 10 days in the treatment of CAP and acute exacerbations of chronic bronchitis (AECB). Azithromycin has a longer half-life than clarithromycin, and concentrates in tissues, achieving very low serum levels when administered orally. The dosing regimen for CAP is usually 500 mg for 1 day, followed by 250 mg daily for 4 days. An extended-release preparation allows the administration of 2000 mg as a one-time dose for CAP. For the hospitalized patient, an intravenous preparation of azithromycin is available and is dosed as 500 mg daily, with the duration defined by the clinical course of the patient, but usually for 7 to 10 days.[3] Because of its intravenous administration, the serum levels achieved have been adequate for the therapy of bacteremic pneumococcal pneumonia.[53] During inpatient CAP therapy, the fluid infusion volume of erythromycin is greater with erythromycin than azithromycin and has occasionally led to more volume overload and cardiac complications with erythromycin.

Solithromycin is a novel fourth-generation macrolide effective against *S. pneumoniae*, *H. influenzae*, and atypical pathogens. In two recent, double-blind, randomized, controlled, noninferiority trials, solithromycin was comparable to oral moxifloxacin in patients with mild to moderate CAP (Pneumonia Severity Index classes II–IV).[54,55] Elevated liver enzymes were seen in the first trial, SOLITAIRE-ORAL (800-mg oral loading dose then 400 mg for 5 days), but not with the follow up study, SOLITAIRE-IV (400 mg IV with option of switching to oral dose as with SOLITAIRE-ORAL). Because of concerns about hepatic toxicity, this drug is not currently approved for use in the United States or Europe.

Clinical studies of CAP have consistently shown a benefit of using macrolide therapy, usually in conjunction with a β-lactam, but the mechanism for this favorable effect is not known.[3,56] The addition of a macrolide to a β-lactam has reduced mortality for hospitalized CAP patients, including those with pneumococcal bacteremia and those with pneumococcal pneumonia and a high level of inflammation. Speculation has included the possibility of coverage for atypical pathogen coinfection, a possibility supported by studies that have found the benefit of the addition of a macrolide to vary year to year.[50] Another explanation is the anti-inflammatory effects possessed by macrolides, which may account for their benefit in improving quality of life in patients with cystic fibrosis and bronchiectasis. Macrolides have a myriad of other effects, including interference with "quorum sensing" between bacteria, which could inhibit the in vivo proliferation of *P. aeruginosa* after colonization has occurred.[57]

Although macrolides remain an important therapeutic option for community respiratory tract infections, pneumococcal resistance is becoming increasingly common, especially in patients who have received an agent of this class in the past 3 months.[58,59] In addition, macrolide resistance can also coexist with penicillin resistance with up to 30% to 40% of penicillin-resistant pneumococci also erythromycin-resistant. The clinical relevance of these in vitro findings remains to be defined, particularly if macrolides are used in combination with a β-lactam antibiotic. However, there are two forms of pneumococcal macrolide resistance, one involving efflux of the antibiotic from the bacterial cell and the other involving altered ribosomal binding of the antibiotic. The former mechanism is associated with much lower levels of resistance than the latter and is present in two-thirds of the macrolide-resistant pneumococci in the United States. The latter form of resistance is less common and, when present, makes macrolide therapy for pneumococcal infection ineffective.

Clindamycin

This agent inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit, and can be either bactericidal or bacteriostatic depending on the target pathogen site of infection and drug level achieved. Available both orally and intravenously, clindamycin is approved for use in the therapy of sepsis and intra-abdominal infections, but it may be valuable in the therapy of CAP in specific patient populations. It is active against anaerobes and can be used in some patients with aspiration pneumonia and lung abscess. It is active against pneumococcus and *S. aureus* and can be used in patients with penicillin allergy. It is also effective at inhibiting bacterial toxin production and can be added to vancomycin to inhibit toxin production in patients with necrotizing pneumonia due to community-acquired methicillin-resistant *S. aureus*. The most common side effects are nausea, vomiting, diarrhea, and an increased risk of *Clostridium difficile* infection.

■ Tetracyclines

The tetracycline and doxycycline are bacteriostatic agents that act by binding the 30S ribosomal subunit and interfering with protein synthesis. These agents can be used in CAP because they are active against *H. influenzae* and atypical pathogens, but in the United States, pneumococcal resistance to tetracyclines may be approaching 20% and may exceed 50% among organisms with high-level penicillin resistance. Photosensitivity is the major side effect, limiting the use of these agents in sun-exposed patients. This drug still remains as a good alternative to treat patients with suspected atypical pneumonia infection in those with electrocardiographic QT prolongation.

Omadacycline is a recently approved aminomethylcycline with structural modifications to the tetracycline scaffold allowing it to withstand the tetracycline efflux and ribosome protection mechanisms of resistance. In a recent, randomized, double-blind trial in CAP patients (Pneumonia Severity Index risk class of II, III, or IV) comparing omadacycline (100 mg IV every 12 h for two doses, then 100 mg IV every 24 h) to moxifloxacin (400 mg intravenously every 24 h), there was a similar early clinical response with both antibiotics.[60]

Tigecycline is a glycylcycline, which is structurally similar to the tetracyclines, and contains a central four-ring carbocyclic skeleton but is a derivative of minocycline. Tigecycline is bacteriostatic and is a protein synthesis inhibitor that acts by binding to the 30S ribosomal subunit of bacteria, thereby blocking entry of aminoacyl-tRNA into the ribosome during prokaryotic translation.

This drug is approved to treat complicated skin and skin-structure infections and complicated intra-abdominal infections, but it can also be used in CAP caused by *S. pneumoniae*, *H. influenzae*, and *L. pneumophila*. With the exception of gastrointestinal adverse events, tigecycline is generally well tolerated. It is not approved for the therapy of MRSA pneumonia or HAP. Freire et al.,[61] in a randomized, double-blind study including 945 HAP patients, found tigecycline 100 mg per day to be noninferior to imipenem/cilastatin in a modified intent-to-treat analysis but not in the clinically evaluable population and not in VAP. Tigecycline should not be used as monotherapy of VAP, but could be part of a combination when treating resistant *Acinetobacter* strains.[62] Some data suggest that a higher dose (100 mg every 12 h) could be more effective, but this is not approved for clinical use.

■ Trimethoprim–Sulfamethoxazole

This combination antibiotic has been the mainstay of therapy against *Pneumocystis* pneumonia and *Pneumocystis jirovecii*. In the past, given its antimicrobial spectrum, ease of use, and low cost, it was an effective agent for CAP and AECB. It has bactericidal activity against the pneumococcus, *H. influenzae*, and *M. catarrhalis*, but not against atypical pathogens. Recently, it has become less popular because of the emergence of pneumococcal resistance at rates of at least 30%, since 80% to 90% of organisms that are penicillin resistant are also resistant to TMP-SMX. The sulfa component of the drug inhibits the bacterial enzyme responsible for forming the immediate precursor of folic acid, dihydropteroic acid. Trimethoprim is synergistic with the sulfa component and inhibits the activity of bacterial dihydrofolate reductase. TMP-SMX is available in a fixed combination of 1:5 (TMP:SMX), and is dosed as either 80/400 mg or 160/800 mg orally twice a day for 10 days, but the dosage should be adjusted in renal failure. An intravenous preparation also is available. Side effects generally result from the sulfa component and include rash, GI upset, and occasional renal failure (especially in elderly patients).

■ β-Lactam Antibiotics

β-Lactam antibiotics are bactericidal agents that interfere with the synthesis of bacterial cell-wall peptidoglycans by binding to bacterial penicillin-binding proteins. They share a β-lactam ring with structural modifications determining classification: (a) penicillins with the β-lactam ring bound to a five-membered thiazolidine ring; (b) cephalosporins with the β-lactam ring bound to a six-membered dihydrothiazine ring; (c) carbapenems with modifications in the thiazolidine ring (imipenem, ertapenem, doripenem, and meropenem); (d) monobactams with absence of a second ring structure found in the carbapenems (aztreonam). These agents can also be combined with β-lactamase inhibitors such as sulbactam, tazobactam, vaborbactam, relebactam, avibactam, or clavulanic acid to create the β-lactam/β-lactamase inhibitor drugs, which may overcome the bacterial resistance mechanism of β-lactamase production.

The penicillins used for respiratory tract infections include the natural penicillins (penicillin G and V), the aminopenicillins (ampicillin, amoxicillin), the antistaphylococcal agents (nafcillin, oxacillin), the antipseudomonal agents (piperacillin, ticarcillin), and the β-lactam/β-lactamase inhibitor combinations (ampicillin/sulbactam, amoxicillin/clavulanate, piperacillin/tazobactam, and ticarcillin/clavulanate). Among the antipseudomonal penicillins, piperacillin is the most active agent.

Imipenem, doripenem, and meropenem are the antipseudomonal carbapenems, the broadest-spectrum agents in this class, active against Gram-positives, anaerobes, and Gram-negatives including *P. aeruginosa*. They have shown efficacy for patients with severe pneumonia, both community-acquired and nosocomial. A nonpseudomonal carbapenem, ertapenem also is available and has been used effectively in the therapy of CAP and HAP. Several new preparations have added β-lactamase inhibitors to carbapenems to expand their spectrum of activity against resistant bacteria, including imipenem/relebactam and meropenem/vaborbactam. Aztreonam is a monobactam that is antigenically distinct from the β-lactams and can be used in penicillin-allergic patients. It is only active against Gram-negative organisms, having a spectrum very similar to the aminoglycosides.

The earlier cephalosporins were generally active against Gram-positive bacteria without activity against the more complex Gram-negatives or anaerobes and were susceptible to destruction by bacterial β-lactamases. The newer-generation agents are generally more specialized, with broader-spectrum activity and with resistance to breakdown by bacterial enzymes. The second-generation and newer agents are resistant to bacterial β-lactamases, but cefuroxime may not be an optimal pneumococcal agent if resistance is present.[63] The third-generation agents such as ceftriaxone and cefotaxime are active against penicillin-resistant pneumococci, while ceftazidime is not reliable against the pneumococcus but is active against *P. aeruginosa*. The third-generation agents may induce β-lactamases among certain gram-negatives (especially the *Enterobacteriaceae* spp.) and thus may promote the emergence of resistance during monotherapy. The fourth-generation agent cefepime is active against pneumococci and *P. aeruginosa* and is also less likely to induce resistance among the *Enterobacteriaceae* than the third-generation agents. Ceftaroline is a new, advanced-generation cephalosporin that has been approved for the therapy of CAP with in vitro activity against MRSA. It has bactericidal activity against Gram-positive and -negative pathogens, but also against MRSA and particularly against DRSP. In a meta-analysis of three randomized studies, ceftaroline (600 mg every 12 h) was superior to ceftriaxone (1–2 g every 24 h) for 5 to 7 days in an intention-to-treat analysis in patients with severe pneumonia (odds ratio [OR], 1.66; 95% confidence interval [CI], 1.34–2.06).[64] In another meta-analysis of 5 randomized controlled studies of CAP patients, ceftaroline was superior to ceftriaxone for clinical cure rate (OR, 1.61; 95% CI, 1.31–1.99).[65]

In the last few years, several new therapeutic options have become available for pneumonia, particularly HAP/VAP, with a focus on treating MDR pathogens, including the following:

1. Ceftobiprole, a fifth-generation cephalosporin with extended-spectrum activity against Gram-positive pathogens including methicillin-sensitive *S. aureus* (MSSA), methicillin-resistant coagulase-negative staphylococci, penicillin, and ceftriaxone-resistant *S. pneumoniae* and Gram-negative pathogens such as *P. aeruginosa* and *Enterobacteriaceae*, but limited efficacy against MRSA, *Acinetobacter*, and extended-spectrum β-lactamase (ESBL)-producing Gram-negatives.[66] It is approved in Europe for the treatment of HAP/VAP but not approved in the United States for use in pneumonia. In a randomized study including 706 CAP patients, use of ceftobiprole (500 mg every 8 h) was not inferior to ceftriaxone as monotherapy (2 g every 24 h) or combined with linezolid (600 mg every 12 h) in microbiologic cure rates.[67] In another study including 781 HAP/VAP patients, ceftobiprole 500 mg every 8 h showed similar efficacy to ceftazidime 2 g every 8 h plus linezolid 600 mg every 12 h (49.9% vs. 52.8%; 95% CI for the difference, −10.0 to 4.1).[68] Dose adjustments are needed in patients with moderate to severe renal impairment. In clinical trials, ARC may have led to some patients doing less well with ceftobiprole than with comparator agents.
2. Ceftazidime-avibactam (CEF/AVI) is a combination of a third-generation cephalosporin with a semisynthetic β-lactamase inhibitor. CEF/AVI is active against *P. aeruginosa* as well as a variety of MDR Gram-negatives producing β-lactamases, including Ambler class A (*K. pneumoniae* carbapenemases and ESBL-type enzymes), Ambler class C (AmpC), and some Ambler class D serine enzymes (e.g., oxacillinase OXA-48). This agent is not active against metallo-β-lactamases (MBL) or *Acinetobacter* OXA-like carbapenemases. CEF/AVI is approved by the FDA and EMA for use in HAP/VAP, having been shown to be noninferior to meropenem in a randomized controlled trial of carbapenem-resistant, non-Enterobacteriaceae pneumonia.[69] That trial included 726 nosocomial pneumonia patients, comparing 2000 mg ceftazidime and 500 mg avibactam to meropenem 1000 mg IV every 8 h. Both therapies had similar clinical cure rates (68.8% vs. 73.0%; difference, −4.2%; 95% CI, −10.8 to 2.5).[70] CEF/AVI could also be considered as an alternative to colistin in the treatment of carbapenem-resistant Enterobacteriaceae infections.[71]
3. Ceftolozane-tazobactam (CTZ/TAZ) is a cephalosporin and β-lactamase inhibitor with in vitro activity against multidrug-resistant *P. aeruginosa* and ESBL-producing Enterobacteriaceae. In a randomized controlled trial of CTZ/TAZ in mechanically ventilated patients with Gram-negative nosocomial pneumonia,[72] CTZ/TAZ (2 g ceftolozane plus 1 g tazobactam infused for 1 h every 8 h) was compared with meropenem (1 g infused for 1 h every 8 h). In the study, CTZ/TAZ was highly effective and well tolerated in mechanically ventilated patients with Gram-negative nosocomial pneumonia, with a mortality advantage in those with ventilated HAP and in those with prior unsuccessful antibiotic therapy of the current episode of nosocomial pneumonia. Bacteremic patients and those with *P. aeruginosa* infection had a higher rate of clinical cure if they were treated with CTZ/TAZ. This agent has been approved for HAP treatment by the FDA and EMA. Caution needs to be exercised in patients with impaired renal function.
4. Cefiderocol is a siderophore cephalosporin that binds to iron and enters the bacterial cell using the iron transport system. It is active against many carbapenem-resistant pathogens including *Enterobacteriaceae*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*. In addition, it has activity against *Stenotrophomonas maltophilia*. Cefiderocol is approved for nosocomial pneumonia, including VAP, but showed no survival advantage or higher cure rates compared to meropenem. In another study, patients with VAP had a lower survival than with best available therapy.[73,74]
5. Meropenem-vaborbactam is a combination agent containing an existing β-lactam antibiotic (meropenem) with a cyclic boronate, non–β-lactam/β-lactamase inhibitor (vaborbactam). It has activity against Gram-negative microorganisms, including those with extended-spectrum β-lactamases and *K. pneumoniae* carbapenemases. However, it does not have activity against metallo-β-lactamase- and oxacillinase-producing strains. Although not approved for VAP, in a trial that included mechanically ventilated

patients, with carbapenem-resistant Enterobacteriaceae (CRE), meropenem-vaborbactam was compared with best available therapy (usually colistin) and showed an advantage for clinical cure with the new agent.[75]

6. Imipenem-relebactam (IR) is a combination agent containing an existing β-lactam antibiotic (imipenem-cilastatin) with a non–β-lactam/β-lactamase inhibitor (relebactam) and activity against Gram-negative microorganisms, including Ambler class C, extended-spectrum β-lactamases, and *K. pneumoniae* carbapenemases. However, it does not have activity against metallo-β-lactamase- and oxacillinase-producing strains. In a phase 3 trial comparing IR to piperacillin-tazobactam in 537 patients with nosocomial pneumonia, half being mechanically ventilated, the two therapies were equivalent for clinical cure and mortality.[76] Among the subgroup of those mechanically ventilated at baseline, survival was higher with IR.

■ Fluoroquinolones

Fluoroquinolones are bactericidal agents that act by interfering with bacterial DNA gyrase and/or topoisomerase IV, leading to impaired DNA synthesis repair and transcription and other cellular processes resulting in bacterial cell lysis. The earlier quinolones (such as ciprofloxacin and ofloxacin) are active primarily against DNA gyrase, which accounts for efficacy against Gram-negative bacteria. The newer agents (levofloxacin and moxifloxacin) bind both DNA gyrase and topoisomerase IV, accounting for efficacy against even drug-resistant Gram-positive organisms, including drug-resistant *S. pneumoniae* (DRSP). Resistance to fluoroquinolones can occur via a variety of mechanisms including mutations in the topoisomerase enzymes, altered permeability of the bacterial cell wall, or efflux of the antibiotic from inside of the bacteria.[77]

The fluoroquinolones are active against β-lactamase–producing organisms like *H. influenzae* and *M. catarrhalis,* making them very useful for patients with AECB.

Both levofloxacin and moxifloxacin have extended the activity of the quinolones with enhanced Gram-positive activity as well as by being more active against *C. pneumoniae* and *M. pneumoniae* when compared with the older agents. They are also highly effective against *L. pneumophila* and may be the drug of choice for this organism. For *P. aeruginosa*, as in certain patients with CAP, AECB, and HAP, only ciprofloxacin (750 mg twice daily orally or 400 mg every 8 h IV) or levofloxacin (750 mg orally or IV daily) are active enough for clinical use. Since some agents (e.g., ciprofloxacin) have borderline activity against the pneumococcus, if they are used for AECB or CAP, the dose should probably be optimized to either 750 mg twice daily of ciprofloxacin for AECB or 750 mg once daily of levofloxacin for CAP or AECB.

Levofloxacin and ciprofloxacin, but not moxifloxacin, are renally excreted and thus require dosage adjustment in patients with renal insufficiency. These agents also differ in the degree of protein binding. The relevance of this feature to clinical outcome is uncertain, but agents like levofloxacin and moxifloxacin are not highly protein bound and have higher free serum concentrations. Although the newer agents are highly active against both penicillin-sensitive and -resistant pneumococci, there is concern that widespread use may increase pneumococcal resistance to these agents. Up to 20% of pneumococcal strains have quinolone resistance–determinant genes present but have not developed full resistance.[77] Risk factors for quinolone resistance among pneumococci are recent hospitalization, recent quinolone therapy, and residence in a nursing home.

Several new quinolones are in development. Nemonoxacin is a novel nonfluorinated quinolone; in a phase 3 study of CAP patients randomized to nemonoxacin ($n = 356$) or levofloxacin ($n = 171$) there was no difference in clinical or microbiologic cure rates between the groups at 7 to 10 days, with comparable adverse side effects.[78] In a meta-analysis including 3 randomized controlled studies, cure rates, microbiologic response, and treatment-emergent adverse effects were similar in CAP patients treated with nemonoxacin (500 or 750 mg) compared to levofloxacin.[79] Major side effects are QTc interval prolongation and myelotoxicity. Delafloxacin is another novel fluoroquinolone with activity against MRSA, *Enterococcus faecalis*, *C. pneumoniae*, *Mycoplasma* spp., and *Legionella* spp. In a phase 3 study in CAP patients, there was a 16-fold greater activity with delafloxacin compared to moxifloxacin for Gram-positive and fastidious Gram-negative pathogens, with retained activity against resistant phenotypes found in *S. pneumoniae* (penicillin-, macrolide-, and multiple-drug resistant), *Haemophilus* species (β-lactamase–producing, macrolide-nonsusceptible), and *S. aureus* (MRSA, fluoroquinolone-nonsusceptible MSSA).[80] Zabofloxacin is another oral fluoroquinolone with greater in vitro activity against Gram-positive agents than moxifloxacin. In a phase 3 trial, zabofloxacin 367-mg tablet orally once daily for 5 days (plus 2 days placebo) was noninferior (86.7% vs. 86.3%) to moxifloxacin 400 mg once daily for 7 days for patients with chronic obstructive pulmonary disease exacerbation.

■ Aminoglycosides

The aminoglycosides are bactericidal agents that act by binding to the 30S ribosomal subunit of bacteria, thus interfering with protein synthesis. Aminoglycosides have primarily a Gram-negative spectrum of activity and are usually used in combination with other agents targeting difficult organisms such as *P. aeruginosa* or other resistant Gram-negative bacteria. When combined with certain β-lactam agents they can achieve antibacterial synergy against *P. aeruginosa*. Amikacin is least susceptible to enzymatic inactivation by bacteria, whereas tobramycin is more active than gentamicin against *P. aeruginosa*. Aminoglycosides penetrate poorly into lung tissue and can be inactivated by the acidic environment of pneumonic lung tissue, and are primarily used as part of combination therapy. Because of poor penetration, some investigators have used nebulized aminoglycosides for the therapy and/or prevention of Gram-negative pneumonia, but clinical data showing efficacy are limited for this application. Clinical trials conducted for nosocomial pneumonia therapy revealed that the use of an intravenous aminoglycoside with a β-lactam antibiotic compared to a β-lactam monotherapy alone was not more effective and the combination did not prevent the emergence of *pseudomonal* resistance.[81] In the treatment of bacteremic *pseudomonal* pneumonia, aminoglycoside combination therapy may be more effective than monotherapy.

As discussed above, aminoglycosides kill in a concentration-dependent fashion and can be dosed once daily to optimize killing while minimizing toxicity (primarily renal insufficiency). In clinical practice, this has not been proven to occur, and once-daily dosing is comparable in efficacy and nephrotoxicity to multiple-dose regimens. When aminoglycosides are used, it is necessary to monitor serum levels to minimize the occurrence of acute renal failure. Peak concentrations correlate with efficacy but only have meaning with multiple daily doses, and their utility in once-daily regimens has not been established. Trough concentrations are monitored to minimize toxicity and probably should be followed regardless of dosing regimen.

A semisynthetic aminoglycoside (referred to as a neoglycoside), plazomicin, may become a therapeutic option for pneumonia, but it is currently approved only for complicated urinary tract infections. It is also a bactericidal agent, with concentration-dependent killing, acting to inhibit bacterial protein synthesis at the 30S ribosomal subunit, after binding to the 16S subunit.[82] It has broad activity against Gram-negatives and Gram-positives, including MRSA, *P. aeruginosa* (more active than amikacin), Enterobacteriaceae, *K. pneumoniae*, and some *Acinetobacter* spp. For all these pathogens, plazomicin is more active than other aminoglycosides. It has similar concerns about nephrotoxicity and limited data for therapy of VAP, being similar in efficacy to colistin.

■ Therapy of Methicillin-Resistant *S. aureus* Infections

Vancomycin and Other Older Agents

MRSA has emerged as an important pathogen in patients with nosocomial pneumonia, particularly VAP, and also in association with necrotizing post-influenza community-acquired pneumonia. In the past, vancomycin was the agent used most commonly against this pathogen. However, there have been concerns about the limited efficacy of vancomycin, primarily because of poor penetration into respiratory secretions. In addition, vancomycin is dosed intermittently with the goal of maintaining trough concentrations between 15 and 20 μg/mL; in critically ill patients this level may be associated with nephrotoxicity and may not be effective for organisms with MIC values >1 μg/mL. Vancomycin is often underdosed in critically ill patients with pneumonia and ARC.[83] Higher doses may be required in those receiving RRT. Use of a weight-based loading dose (approximately 35 mg/kg, using actual body weight) followed by continuous infusions (adjusted according to the CrCl) has been advocated by some investigators to rapidly achieve therapeutic vancomycin concentrations in critical illness, but without proven benefit. In patients with community-acquired MRSA, necrotizing pneumonia may develop due to damage caused by bacterial exotoxins. Toxin inhibition does not occur with vancomycin and can be achieved by adding clindamycin—or alternatively by monotherapy with linezolid (below), which can inhibit bacterial toxin production.

Quinupristin/dalfopristin has been tested in patients with VAP and was not as effective against MRSA as vancomycin in spite of good in vitro activity. There are several other agents in various stages of development that have activity against MRSA that have not been proven to be useful for the therapy of respiratory tract infections (see below). This includes daptomycin, which is inactivated by pulmonary surfactant, thus explaining a lack of efficacy in pneumonia therapy trials (and which is never recommended for pneumonia). Tigecycline and ceftaroline are available, but efficacy of these agents in the therapy of MRSA pneumonia is not known.

Linezolid

Linezolid is the first agent in a newer antibiotic class, the oxazolidinones, which act by inhibiting bacterial protein synthesis and have activity against MRSA. Oxazolidinones bind to the 50S ribosomal subunit, preventing binding to transfer RNA and blocking formation of the 70S initiation complex. Oxazolidinones inhibit production of antibacterial toxins such as the Panton-Valentine leukocidin, which can be produced by community-acquired MRSA strains. Linezolid is active against MRSA as well as against DRSP and vancomycin-resistant enterococci (VRE) (both *Enterococcus faecium* and *Enterococcus faecalis*). This agent has a high bioavailability with similar serum levels with oral or intravenous therapy. Renal and nonrenal clearance occurs, and dosing adjustments are not needed for patients with renal failure.

Given the increased recognition of the unique pharmacokinetic–pharmacodynamic changes in critical illness, empiric use of linezolid instead of high-dose vancomycin has a theoretical advantage for the treatment of MRSA pneumonia. One prospective, double-blind, controlled trial involving patients with confirmed MRSA pneumonia—randomized to receive either linezolid (600 mg 12 hourly) or vancomycin (15 mg/kg every 12 h with dose adjustment on the basis of trough levels) for 7 to 14 days—showed higher clinical success with linezolid and similar 60-day mortality rates between groups.[84]

Linezolid is a reasonable alternative for patients with treatment failure while receiving vancomycin, for MRSA isolates with vancomycin MIC values >2 μg/mL, for patients with allergic reactions, or for those with high risk of vancomycin-induced nephrotoxicity.[85] Side effects are not common and include nausea, diarrhea, anemia, and thrombocytopenia (especially with prolonged use). It is a weak monoamine oxidase inhibitor. Tedizolid is a synthetic oxazolidinone active against MRSA, linezolid-resistant MRSA, and VRE. It is approved for acute bacterial skin and soft tissue infections, but its use is being explored for patients with HAP/VAP.[86] It may cause less thrombocytopenia than linezolid.

Telavancin

Telavancin is a new lipoglycopeptide with rapid, concentration-dependent killing activity, adequate lung penetration, and bactericidal action against Gram-positives including VRE and MRSA. In a prospective, randomized, double-blind trial, telavancin was compared against vancomycin in the treatment of MRSA HAP in 1503 patients.[87] Higher cure with monomicrobial *S. aureus* infection was seen with telavancin, and it was more effective than vancomycin for MRSA with vancomycin MIC values >1 μg/mL. The ATTAIN studies comparing telavancin (10 mg/kg every 24 h) versus vancomycin (1 g every 12 h) for the treatment of HAP/VAP reported similar mortality and safety profile with both drugs, except higher mortality in the telavancin arm for those with moderate to severe renal impairment.[88] Thus, telavancin is an alternative for vancomycin in treatment of MRSA nosocomial pneumonia except in those with renal impairment.

■ Polymyxins

Polymyxins are bactericidal antibiotics used in the treatment of Gram-negative bacterial infections that work in a concentration-dependent fashion, and include polymyxin B and E—the latter known as colistin. After binding to lipopolysaccharide (LPS) in the outer membrane of Gram-negative bacteria, polymyxins disrupt both the outer and inner membranes, causing increased permeability of the bacterial cell wall to other antibiotics. Gram-negative bacteria can develop resistance to polymyxins through various modifications of the LPS structure that inhibit the binding of polymyxins to LPS.

Polymyxins can be used for pneumonia caused by strains of MDR *P. aeruginosa*, *Acinetobacter* resistant to carbapenems, or carbapenemase-producing *Enterobacteriaceae*.[89] Polymyxins are not absorbed from the gastrointestinal tract, and therefore they are administered intravenously or by inhalation. Elimination is primarily renal, and they are 50% protein bound. Major side effects include nephrotoxicity and neurotoxicity (neuromuscular block, confusion, ataxia, visual disturbances, and dizziness).

A retrospective matched case-control study comparing IV colistin or aerosolized (AS) plus IV colistin in the treatment of VAP by MDR pathogens, in which *A. baumannii* was the most common pathogen, followed by *Klebsiella pneumonia* and *P. aeruginosa*, showed no significant differences between the groups for eradication of pathogens, clinical cure, and mortality.[90] Optimal pneumonia dosing is not fully established. Colistin dosing is from 3 million (240 mg colistimethate) units to 5 million (400 mg colistimethate) units every 8 h. In the therapy of *Acinetobacter*, polymyxins may be more effective when combined with sulbactam.

■ Lefamulin

This agent is in the new pleuromutilin class of antibiotics and is a novel semisynthetic compound. It has activity against MRSA, VRE, DRSP, *L. pneumophila*, *C. pneumoniae*, and *Mycoplasma pneumoniae*. It was approved for use in CAP based on the phase 3 LEAP 2 randomized clinical trial examining early clinical response in CAP patients (Pneumonia Severity Index risk class of II, III, or

IV) receiving 5 days of oral lefamulin, where it was noninferior to 7-day oral treatment with moxifloxacin.[91]

Aerosolized Antibiotics for Respiratory Tract Infections

Lung penetration of many intravenous antibiotics, including aminoglycosides and colistin, is limited despite appropriate antibiotic administration. Increased dosages and prolonged duration of therapy used to treat resistant organisms can be associated with greater systemic toxicity with an increased risk of development of antimicrobial resistance.[92] Aerosolized antibiotics might address these concerns by direct delivery to the site of respiratory infection, particularly for agents that penetrate poorly into the lung with systemic administration. Direct delivery of antibiotics is usually achieved by nebulization, which achieves high intrapulmonary concentrations with generally low systemic absorption, reducing the risk of systemic toxicity. The majority of studies of inhaled antibiotics have been done in nonventilated patients with cystic fibrosis, and chronic bronchial infection with *P. aeruginosa*, including patients with bronchiectasis.[93]

The use of this approach in mechanically ventilated patients has been reported for patients with either infectious tracheobronchitis or VAP, particularly when the infections involve highly resistant Gram-negative bacteria (*P. aeruginosa*, *Klebsiella* spp., and *Acinetobacter* spp.) and in whom topical delivery of antibiotics might allow effective therapy of pathogens that cannot be eradicated by systemic therapy. The appropriate dose of aerosolized antibiotics is uncertain but can be calculated using the intravenous dose for that particular medication and adding to it the amount of extrapulmonary drug deposition. When concentration-dependent killing antibiotics are administrated, higher peak tissue concentration is associated with greater bactericidal activity, while time-dependent antibiotics are required to maintain lung tissue concentrations above the MIC of the target organism for a prolonged period.[94,95]

Antibiotics can be administered using ultrasonic, jet, or vibrating mesh nebulizers. Jet nebulizers generate aerosols by using compressed gas, ultrasonic nebulizers use a piezoelectric crystal to agitate a solution at high frequency, and mesh nebulizers use a high-frequency vibrating mesh to pump a solution through tapered holes.[94] Factors that influence lung deposition of nebulized antibiotics during mechanical ventilation include aerosol particle size, type of nebulizer, physical characteristics of the carrying gas, respirator settings, pneumonia severity, and degree of lung aeration.[94] (Penetration of antibiotic into areas of bronchopneumonia differs from consolidation.) Aerosolized particles with median mass aerodynamic diameter of 1 to 5 μm can reach the distal bronchioles and alveolar space. A volume control mode of mechanical ventilation has been used with a constant inspiratory flow but may require sedation during aerosol administration. Nebulization should be synchronized to the inspiratory cycle, while the inspiratory to expiratory ratio is maintained at 1:1, and the nebulizer can be placed in the inspiratory tubing or in line between the endotracheal tube and the Y connector.[96,97] Conventional humidifiers need to be used in the ventilator, but humidification is discontinued during nebulization. While the optimal method of administration of aerosol therapy is unknown, most studies have shown that nebulization can be effective and achieve more uniform distribution than direct instillation and, with modern delivery methods, more than 50% of the nebulized dose is retained in the lung. In experimental studies, it has been shown that the alveolar capillary membrane permeability is markedly increased during lung parenchymal infection.[94] Thus, inhaled antibiotics like aminoglycosides and cephalosporins, but not colistin, could be absorbed into the systemic circulation, with some potential for toxicity.

Several studies have shown that inhaled antibiotics can be used as either sole therapy or adjunctive (to intravenous) therapy for MDR Gram-negative VAP.[90,98] Cure rates greater than 60% have been reported, especially with the use of the vibrating mesh plate, small-particle nebulizer. Aerosolized antibiotics have shown efficiency in studies to treat the lung infection as well as the bacterial reservoir within the biofilm of the endotracheal tube. One randomized trial compared nebulized amikacin and ceftazidime (without systemic therapy) in the treatment of *pseudomonal* VAP to intravenous treatment with the same medications. The study showed that nebulized medications were able to treat VAP but prevented treatment-related acquisition of antibiotic resistance that was seen in patients receiving intravenous antibiotics.[99] Another prospective randomized trial examined the impact of adjunctive inhaled amikacin, using a vibrating mesh plate nebulizer in patients with VAP, many of whom had MDR Gram-negative infection, and showed that inhaled therapy led to less systemic antibiotic use and more de-escalation than adjunctive inhaled saline.[100]

In a meta-analysis including 11 studies, the authors found that aerosolized colistin or aminoglycosides led to a higher resolution rates for patients with resistant pathogens, but not in those with sensitive pathogens.[101] In a more recent, randomized, placebo-controlled study of adjunctive inhaled amikacin/fosfomycin (300 mg amikacin, 120 mg fosfomycin inhaled every 12 h for 10 days) in 143 patients with Gram-negative VAP, the authors found no difference in the Clinical Pulmonary Infection Score (CPIS), mortality, or clinical cure between the standard of care arm and the adjunctive inhaled treatment arm.[102] Another large, randomized, blind study of 712 patients with Gram-negative VAP compared adjunctive inhaled amikacin (BAY41-6551) to inhaled placebo and demonstrated no impact on mortality at 32 days.[94] In both of the studies mentioned above, *Acinetobacter baumannii* and *P. aeruginosa* were the predominant respiratory isolate with a trend showing decreased need for antibiotic escalation with inhaled treatment.

The most recent IDSA/ATS guidelines on nosocomial pneumonia gave a weak recommendation for the addition of inhaled colistin and aminoglycosides to systemic antibiotics for patients with nonresponding Gram-negative VAP with MDR pathogens.[4] In mechanically ventilated patients, even though local antibiotic administration has been successful, there has been concern about the emergence of MDR Gram-negatives with nebulized antibiotic therapy. Most current studies of VAP using either aminoglycosides or polymyxin B have not shown resistance to emerge. One side effect of aerosolized antibiotics has been bronchospasm, which can be induced by the antibiotic or the associated diluents present in certain preparations.

PRINCIPLES OF THERAPY FOR RESPIRATORY TRACT INFECTIONS

Principles of therapy underlying treatment of community-acquired, healthcare-associated, and hospital-acquired pneumonia are considered below.

Community-Acquired Pneumonia

Empiric therapy for CAP is selected by categorizing patients on the basis of the presence or absence of cardiopulmonary disease or other specific "modifying" factors that make certain pathogens more likely, severity of illness, and place of therapy (outpatient, inpatient, ICU). Table 125-2 describes the common pathogens causing CAP in specific patient populations. Figure 125-1 describes antibiotic preferences for the treatment of CAP in an outpatient setting, based on patient characteristics and risk factors. Unlike prior guidelines, newer guidelines allow for β-lactam monotherapy in low-risk outpatient CAP patients. Figure 125-2 describes the antibiotic preferences for the treatment of pneumonia for non-ICU hospitalized patients (hemodynamically stable) based on risk factors and allergy status.

Modifying factors that increase the risk for infections with specific pathogens include the following:

TABLE 125-2 Common Pathogens Causing CAP in Specific Patient Populations (in Order of Decreasing Frequency)

Outpatient, No Cardiopulmonary Disease or Modifying Factors	*S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae* (alone or as mixed infection), *H. influenzae*, respiratory viruses, others (*Legionella* sp., *M. tuberculosis*, endemic fungi)
Outpatient, with Cardiopulmonary Disease	All of the above plus DRSP, enteric Gram-negatives, and possibly anaerobes (with aspiration)
Inpatient, with Cardiopulmonary Disease and/or Modifying Factors	*S. pneumoniae* (including DRSP), *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, mixed infection (bacteria plus atypical pathogen), enteric Gram-negatives (which can include *P. aeruginosa*), anaerobes (aspiration), viruses, *Legionella* sp., others (*M. tuberculosis*, endemic fungi, *Pneumocystis jirovecii*)
Inpatient, with No Cardiopulmonary Disease or Modifying Factors	All of the above, but DRSP and enteric Gram-negatives are not likely. These patients are rarely admitted to the hospital.
Severe CAP, with No Risks for *P. aeruginosa*	*S. pneumoniae* (including DRSP), *Legionella* sp., *H. influenzae*, enteric Gram-negative bacilli, *S. aureus*, *M. pneumoniae*, respiratory viruses, others (*C. pneumoniae*, *M. tuberculosis*, endemic fungi)
Severe CAP, with Risks for *P. aeruginosa*	All of the pathogens above, plus *P. aeruginosa*

MDR: Hospitalization for 2 or more days in the past 90 days, broad-spectrum antibiotics within the past 3 months, immune suppression, poor functional status, admission to an ICU with a high rate of MDR organisms, residence in a nursing home or long-term care facility, or regular visits to a hospital clinic or hemodialysis center. In newer guidelines, an important risk factor is prior respiratory tract isolation of MRSA or *P. aeruginosa*.[3]

DRSP: Age >65 years, β-lactam therapy within the past 3 months, alcoholism, immunosuppressive illness (including therapy with corticosteroids), multiple medical comorbidities, and exposure to a child in a day care.

Enteric Gram-negative bacteria: Residence in a nursing home, underlying cardiopulmonary disease, multiple medical comorbidities, and recent antibiotic therapy. Specific risks for *P. aeruginosa include* structural lung disease (bronchiectasis), corticosteroid therapy (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, and malnutrition. Oral anaerobes occur in the presence of poor dental hygiene.

Post-influenza pneumonia can be caused by *S. aureus* (including community-acquired MRSA), *H. influenzae*, *or* pneumococcus.

From the available data, either a fluoroquinolone or a β-lactam/macrolide combination regimen is therapeutically equivalent in nonsevere CAP. Although not proven, it may be useful to use these two types of regimens interchangeably, striving for “antibiotic heterogeneity” and being sure to select an agent in a different class from those the patient received in the past 3 to 6 months. If patients have received a macrolide, fluoroquinolone, or penicillin in the past 3 months, then a subsequent infection with pneumococcus is more likely to be resistant to the agent received in the past than to other agents.[3] Although oral quinolones may be as effective as intravenous quinolones for admitted

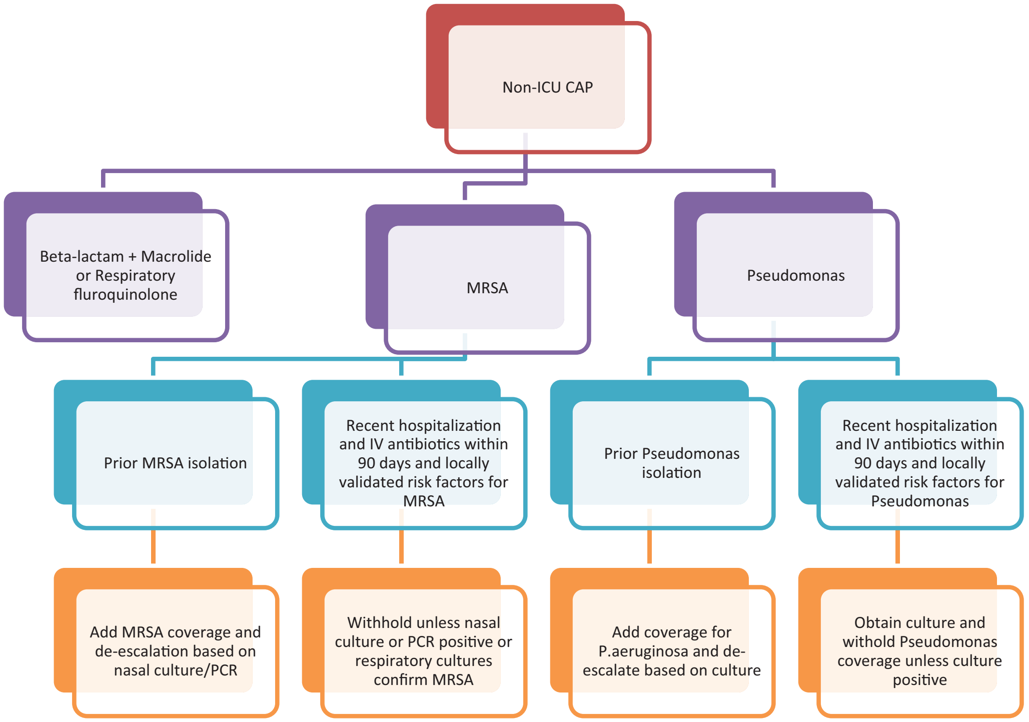
Figure 125-1 Antibiotic preferences for outpatient CAP management based on patient risk factors. Risk factors include prior respiratory isolation of MRSA or *P. aeruginosa*, recent hospitalization, and IV antibiotics within 90 days. Comorbid conditions are chronic heart, lung, liver, or renal disease, as well as alcoholism, malignancy, asplenia, or diabetes mellitus. **Approach to antibiotic selection and dosage for outpatient CAP therapy:** Amoxicillin 1 g three times daily, amoxicillin/clavulanate 500 mg/125 mg three times daily, amoxicillin/clavulanate 875 mg/125 mg twice daily, 2,000 mg/125 mg twice daily, cefpodoxime 200 mg twice daily, cefuroxime 500 mg twice daily, doxycycline 100 mg twice daily, azithromycin 500 mg on first day then 250 mg daily, clarithromycin 500 mg twice daily, or clarithromycin ER 1,000 mg daily, Levofloxacin 750 mg daily, moxifloxacin 400 mg daily.



Non-ICU CAP
Beta-lactam + Macrolide or Respiratory fluroquinolone
MRSA
Pseudomonas
Prior MRSA isolation
Recent hospitalization and IV antibiotics within 90 days and locally validated risk factors for MRSA
Prior Pseudomonas isolation
Recent hospitalization and IV antibiotics within 90 days and locally validated risk factors for Pseudomonas
Add MRSA coverage and de-escalation based on nasal culture/PCR
Withhold unless nasal culture or PCR positive or respiratory cultures confirm MRSA
Add coverage for P.aeruginosa and de-escalate based on culture
Obtain culture and withold Pseudomonas coverage unless culture positive

Standard regimen: Beta-lactams + Macrolide or Respiratory fluroquinolone. Penicillin allergy - aztreonam 2 g every 8 h. Ampicillin/sulbactam 1.5–3 g every 6 h, cefotaxime 1–2 g every 8 h, ceftriaxone 1–2 g daily, or ceftaroline 600 mg every 12 h, AND Azithromycin 500 mg daily or clarithromycin 500 mg twice daily Or Levofloxacin 750 mg daily or moxifloxacin 400 mg daily.
MRSA: vancomycin 15 mg/kg every 12 h and adjusted to trough 15–20 or linezolid 600 mg every 12 h.
Pseudomonas: piperacillin- tazobactam 4.5 g every 6 h, cefepime 2 g every 8 h, ceftazidime 2 g every 8 h, imipenem 500 mg every 6 h, meropenem 1 g every 8 h, aztreonam 2 g every 8 h.

Figure 125-2 Antibiotic preferences for hospitalized CAP management (non-ICU) based on patient risk factors and allergies.

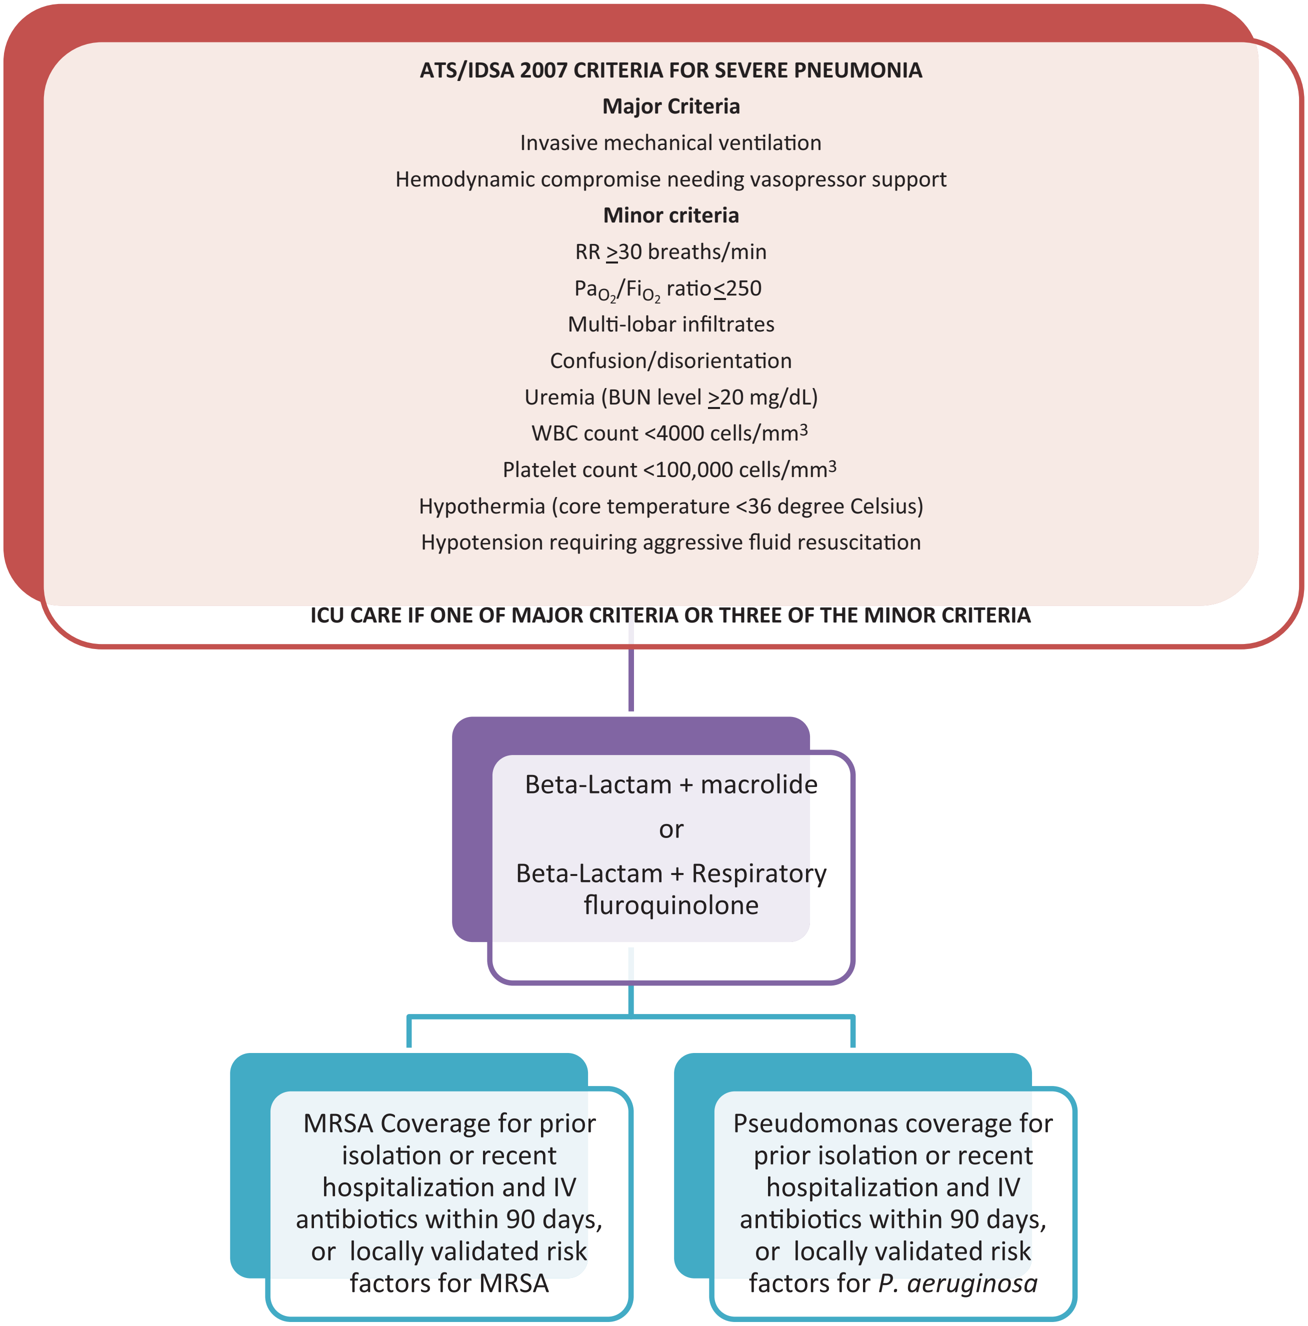
patients with moderately severe illness, most of these patients should receive initial therapy intravenously to be sure that the medication has been absorbed. Once the patient shows a clinical response, oral therapy can be initiated. Selected inpatients with mild to moderate disease can initially be treated with the combination of an intravenous β-lactam and an oral macrolide, switching to exclusively oral therapy once the patient shows a good clinical response.

The most recent updated IDSA/ATS guidelines recommend the use of dual antibiotics: a β-lactam plus either a macrolide or a respiratory quinolone (levofloxacin or moxifloxacin) for patients with severe pneumonia in the ICU with no risks for drug-resistant organisms.[3] Figure 125-3 shows antibiotic preferences to treat CAP in ICU patients based on risk factors and allergy status. In the ICU population, all individuals should receive combination therapy directed at DRSP and atypical pathogens; only those with appropriate risk factors should have coverage for *P. aeruginosa*. Monotherapy should not be used in any ICU admitted CAP patient. In the therapy of *P. aeruginosa*, combination therapy is often needed, but a quinolone may not always be a good choice, given antimicrobial resistance patterns at many hospitals.

In the empiric therapy of CAP, there is a limited need for routine therapy against MRSA; however, a strain of this organism (community-acquired [CA] MRSA) has been described to cause a severe, necrotizing form of CAP after influenza.[18] Although the frequency of this organism is currently low, vigilance is needed for identifying this organism. Optimal therapy for CA-MRSA is uncertain, but the organism produces exotoxins and may be best treated by using both an antibiotic and a toxin production inhibitor. This can be done using linezolid alone or vancomycin with clindamycin. The IDSA/ATS 2019 guidelines recommend empiric coverage for *Pseudomonas aeruginosa* and MRSA based on locally validated epidemiologic risk factors and data about prior isolation of either pathogen. However, for those without prior isolation of either pathogen, empiric therapy directed at them is withheld in those outside the ICU, even with risk factors, pending culture data—but for those in the ICU, empiric therapy for these pathogens is recommended for those at risk, but then adjusted depending on culture data.[3]

These algorithms suggest that all patients should receive empiric therapy that provides coverage for atypical pathogens, based on outcome studies showing improved survival with this approach, and may reflect a high frequency of coinfection by atypical pathogens. Quinolones are preferred over macrolides if *Legionella* is suspected.[103] The current IDSA/ATS 2019 guidelines do not recommend adding additional anaerobic coverage for suspected aspiration pneumonia, as the majority of aspiration pneumonia episodes are caused by Gram-negative pathogens.[3]

Prior studies have shown that combination therapy with a macrolide appeared to have a modest mortality benefit in *S. pneumoniae* bacteremia.[104–107] Sligl et al. found in a meta-analysis of severe CAP patients that combination therapy with a macrolide and β-lactam was associated with reduced mortality compared to other regimens.[108] However, more recent data in non-ICU patients, comparing β-lactam monotherapy to β-lactam–macrolide and fluoroquinolone monotherapy strategies, found no statistical difference in 90-day mortality with the addition of a macrolide.[109] Similarly, another systematic review including 16,884 patients found no difference in outcomes between the use of a β-lactam plus macrolide versus β-lactam plus fluoroquinolone.[110] In general, monotherapy is avoided in ICU



ATS/IDSA 2007 CRITERIA FOR SEVERE PNEUMONIA
Major Criteria
Invasive mechanical ventilation
Hemodynamic compromise needing vasopressor support
Minor criteria
RR ≥30 breaths/min
Pa_{O_2}/Fi_{O_2} ratio ≤250
Multi-lobar infiltrates
Confusion/disorientation
Uremia (BUN level ≥20 mg/dL)
WBC count <4000 cells/mm3
Platelet count <100,000 cells/mm3
Hypothermia (core temperature <36 degree Celsius)
Hypotension requiring aggressive fluid resuscitation
ICU CARE IF ONE OF MAJOR CRITERIA OR THREE OF THE MINOR CRITERIA
Beta-Lactam + macrolide
or
Beta-Lactam + Respiratory fluroquinolone
MRSA Coverage for prior isolation or recent hospitalization and IV antibiotics within 90 days, or locally validated risk factors for MRSA
Pseudomonas coverage for prior isolation or recent hospitalization and IV antibiotics within 90 days, or locally validated risk factors for *P. aeruginosa*

Figure 125-3 Antibiotic preferences for inpatient-ICU-admitted CAP management based on patient risk factors and allergies.

CAP patients, as effective dosing and the safety of a single agent have not been established and guideline-concordant treatment has been consistently effective in reducing CAP mortality.[111]

■ De-Escalation of Antibiotic Therapy in Cap Patients

The IDSA/ATS 2019 guidelines recommend de-escalation of antibiotics in those with no evidence of bacterial superinfection and clinical stability after 48 to 72 h of initiation of antibiotics.[3] Biomarkers such as procalcitonin have been employed to help aid antibiotic de-escalation without an increase in either mortality or treatment failure.[112–115] In a recent meta-analysis of CAP patients, there was no difference in clinical cure rates between short course treatment defined as ≤6 days versus treatment for ≥7 days irrespective of patient setting or severity of pneumonia.[116] Thus, the current guidelines endorse clinicians to continue antibiotics until the patient achieves clinical stability and the duration is not less than 5 days.[3]

■ Hospital-Acquired Pneumonia

Prompt empiric therapy should be initiated as soon as there is clinical suspicion of hospital-acquired infection, since mortality is increased if incorrect antibiotics are used or if a delay in antibiotic initiation occurs (Table 125-3).[4] The updated ATS/IDSA 2016 nosocomial pneumonia guidelines recommend noninvasive sampling with semiquantitative cultures (sputum, endotracheal aspirate) to diagnose VAP, rather than invasive sampling (protected brush, BAL) with quantitative cultures prior to initiation of antibiotic therapy.[4] The guidelines also endorse antibiotic dosing to be determined using pharmacokinetic and pharmacodynamic data based on antibiotic blood concentrations and weight-based dosing rather than manufacturer's prescribing information.[4]

Ideally, each ICU should have a tailored antibiogram, based on local data, for the initial antimicrobial therapy to be effective and account for local bacteriologic patterns. Recent exposure to a

TABLE 125-3 Principles of Antibiotic Therapy for Hospital-Acquired Pneumonia

Prompt empiric therapy: initiate when there is clinical suspicion of infection.
Obtain a lower respiratory tract culture (sputum, endotracheal aspirate) prior to initiation of antibiotic therapy.
Refer to local antibiogram and prevalence of MDR pathogens. Consider MRSA coverage if local resistance pattern for methicillin resistance is >10%–20% and double pseudomonal coverage if local resistance pattern of Gram-negatives shows >10% resistance to any of the antibiotics used for monotherapy.
Use a narrow-spectrum agent for patients only at risk for infection with "core pathogens," and with no risk factors for MDR pathogens. Options include ceftriaxone, ampicillin/sulbactam, ertapenem, levofloxacin, or moxifloxacin. For penicillin allergy, use a quinolone or the combination of clindamycin and aztreonam.
Use combination therapy with a broad-spectrum regimen, containing at least two antimicrobials in patients with risk factors for MDR pathogens. Specific choices should be guided by a knowledge of local microbiology patterns. Use an aminoglycoside or an antipseudomonal quinolone (ciprofloxacin or high-dose levofloxacin), *plus* an antipseudomonal β-lactam such as cefepime, ceftazidime, ceftolozane/tazobactam, imipenem, meropenem, or piperacillin-tazobactam. If there is concern about MRSA, add either linezolid or vancomycin.
Use the correct therapy in recommended doses (see text).
Choose an empiric therapy that uses agents from a different class of antibiotics than the patient has received in the past 2 weeks.
Try to de-escalate to monotherapy after initial combination therapy, after reviewing culture data and clinical response. If *Pseudomonas aeruginosa*, consider stopping the aminoglycoside after 5 days and finish with a single agent to which the organism is sensitive. If a nonpseudomonal infection, switch to a single agent that the organism is sensitive to, using imipenem, meropenem, cefepime, ceftolozane/tazobactam, ceftazidime/avibactam, piperacillin/tazobactam, ciprofloxacin, or high-dose levofloxacin.
The drug of choice for *Acinetobacter* is a carbapenem, but colistin should be considered if there is carbapenem resistance.
Consider linezolid as an alternative to vancomycin in patients with proven MRSA VAP, those with renal insufficiency, and those receiving other nephrotoxic medications (e.g., an aminoglycoside).
Consider adjunctive aerosolized aminoglycosides in patients with highly resistant Gram-negative pathogens.

class of antibiotics can predict subsequent resistance to a variety of agents, usually to the same class but occasionally to other classes of agents as well.[117] The 2016 ATS/IDSA nosocomial guidelines emphasize that in patients with suspected HAP (non-VAP), treatment should be modified to the results of microbiologic cultures rather than being treated empirically if culture data are available. On the other hand, if empiric treatment is to be started, it should be based on a local antibiogram and the prevalence of MDR pathogens in that hospital. The risk factors for MDR-specific pathogens in VAP include use of IV antibiotics within 90 days, septic shock at time of VAP, acute respiratory distress syndrome preceding VAP, late-onset VAP, and need for renal replacement therapy prior to VAP onset.[4] Risk factors for MRSA and *Pseudomonasaeruginosa* HAP/VAP include prior IV antibiotic use within 90 days.

The European guidelines for HAP do not endorse all these risk factors and emphasize a high rate (>25%) of local MDR pathogens, a mortality risk of >15%, recent antibiotic therapy for >5 days in the hospital, recent colonization by MDR pathogens, and the presence of septic shock.[118]

When treating patients with HAP/VAP, empiric coverage should include *S. aureus*, *Pseudomonas aeruginosa*, and other Gram-negative bacilli. MRSA coverage should be included if the local prevalence of *S. aureus* isolates is greater than 10% to 20% methicillin resistant by American guidelines and greater than 25% by European guidelines. Two antipseudomonal antibiotics from different classes are used in patients with risk factors for MDR pathogens or if the locally prevalent Gram-negative isolates have more than 10% resistance to any of the antibiotics used for monotherapy, or if a local antibiogram is not available.[4]

A narrow-spectrum regimen can be used for patients at risk for infection with the "core pathogens" (nonresistant enteric Gram-negatives, pneumococcus, *H. influenzae*, and methicillin-sensitive *S. aureus*) and with no risk factors for MDR pathogens, although very few patients fall into this category. Antimicrobial options include ceftriaxone, ampicillin/sulbactam, ertapenem, levofloxacin, or moxifloxacin. For penicillin allergy, a quinolone or the combination of clindamycin and aztreonam can be selected.

Combination therapy with a broad-spectrum regimen containing at least two antipseudomonal agents should be used for patients with risk factors for MDR pathogens. Specific choices should be guided by knowledge of local microbiology patterns and should include an aminoglycoside or an antipseudomonal quinolone (high-dose ciprofloxacin or levofloxacin) and an antipseudomonal β-lactam such as cefepime, ceftazidime, ceftolozane/tazobactam, imipenem, meropenem, or piperacillin/tazobactam. If there is concern about MRSA, a third agent can be added using either linezolid or vancomycin. Linezolid may be the preferred in patients with proven MRSA VAP and renal insufficiency or in those receiving other nephrotoxic medications (such as an aminoglycoside). The newer agents ceftazidime-avibactam, ceftolozane-tazobactam, imipenem-relebactam, meropenem-vaborbactam, and cefiderocol can be used as the β-lactam agent in patients with risk factors for drug-resistant pathogens that are particularly susceptible to these agents, as outlined above. For those with carbapenem-resistant Enterobacteriaceae, the newer agents such as ceftazidime-avibactam, imipenem-relebactam, and meropenem-vaborbactam may be the most effective choices. For organisms that produce metallo-β-lactamases, the most effective choices may be ceftazidime-avibactam and cefiderocol.[119] For those with highly resistant *P. aeruginosa*, the most effective choices may be ceftolozane-tazobactam, ceftazidime-avibactam, and imipenem-relebactam.

Initial therapy should be given in full recommended doses adjusted as needed for renal function: cefepime 2 g every 6 h; imipenem 500 mg every 6 h or 1 g every 8 h; meropenem 1 g every 8 h; piperacillin/tazobactam 4.5 g every 6 h; levofloxacin 750 mg daily or ciprofloxacin 400 mg every 8 h; vancomycin 15 mg/kg every 12 h leading to a trough level of 15 to 20 mg/L; linezolid 600 mg every 12 h; and for aminoglycosides, 7 mg/kg per day of gentamicin or tobramycin and 20 mg/kg of amikacin.[4] Dosing for the newer agents is listed in Table 125-4. As discussed above, these agents should also be dosed using pharmacokinetic and pharmacodynamic principles of prolonged or continuous infusion of β-lactams, particularly if there is concern about organisms with potential drug resistance.

When choosing empiric therapy, it is important to select agents from a different class of antibiotics than the patient has received in the past 2 weeks, with a plan to de-escalate to monotherapy once culture and clinical response data are available. If *P. aeruginosa* is present, consider stopping the aminoglycoside after 3 to 5 days and finish with a single agent to which the organism is sensitive. If it is a

TABLE 125-4 Newer Antibiotics for Treatment of Pneumonia

Drug	Class	Mechanism of Action	Major Pathogens Covered	Dosage	Major Side Effects
Omadacycline	Aminomethylcycline	Inhibits ribosomal proteins and prevents efflux pumps	MRSA, DRSP, atypical pathogens	100 mg IV once daily 200 mg once daily oral	GI side effects
Solithromycin	Fourth-generation macrolide	Binds to 23S ribosomal RNA, preventing bacterial translation	*S. pneumoniae*, *H. influenzae*, atypical pathogens	800-mg loading dose IV followed by 400 mg once daily IV	Hepatotoxicity
Telavancin	Lipoglycopeptide	Cell wall synthesis inhibitor	Gram-positive including MRSA and VRE	10 mg/kg every 24 h IV	Moderate to severe renal impairment
Nemonoxacin	Novel nonfluorinated quinolone	Inhibits DNA gyrase and topoisomerase IV	Gram-positive, Gram-negative, atypical pathogens, MRSA and VRE	500 mg once daily for 7 days	QT prolongation, myelotoxicity
Delafloxacin	Quinolone	Inhibits topoisomerase IV	MRSA, *Enterococcus faecalis*, *C. pneumoniae*, *Mycoplasma* spp., and *Legionella* spp.	300 mg IV q12h for 5–10 days *or* 300 mg IV q12h, then switch to a 450-mg tablet PO q12h for 5–10 days *or* 450 mg PO q12h for 5–10 days	Tendon rupture, peripheral neuropathy, central nervous system effects, exacerbation of myasthenia gravis
Lefamulin	Pleuromutilin	Bacterial protein synthesis inhibition by binding to peptidyl transferase of 50S bacterial ribosome	MRSA, MSSA, VRE, DRSP, *L. pneumophila*, *C. pneumoniae, and Mycoplasma pneumoniae;* Gram-positives, -negatives, and atypicals	150 mg twice daily IV or oral dose of 600 mg twice daily	Hepatotoxicity
Ceftobiprole	Fifth-generation cephalosporin	Inhibits transpeptidase activity and binding of PBPs	MSSA, MRCNS, *H. influenzae*, *M. catarrhalis*, *K. pneumoniae*, *E. coli*, *P. aeruginosa*, and Enterobacteriaceae	500 mg IV every 8 h	Hepatic enzyme elevation, hyponatremia
Ceftaroline	Fifth-generation cephalosporin	Inhibits transpeptidase activity and binding of PBPs	MRSA, MRCNS, DRSP	600 mg IV every 12 h	Infusion-site reactions
Cefiderocol	Siderophore cephalosporin	Binds to iron and enters bacteria through iron channels	Carbapenem- and colistin-resistant *Acinetobacter* and other Gram-negatives	2 g over 3 h, every 8 h × 7–14 days	Allergic reactions, increased all-cause mortality in MDR Gram-negative infection
Ceftolozane-tazobactam (CToZ + TAZ)	Cephalosporin/BLI	Cell wall synthesis inhibitor and binding of PBPs	Gram-negatives, ESBL, AmpC β-lactamases in *Pseudomonas*; no KPC activity	3 g (2000 mg CToZ + 1000 mg TAZ) IV every 8 h	Hypertension, diarrhea
Ceftazidime-avibactam (CAZ-AVI)	Cephalosporin/BLI	Cell wall synthesis inhibitor, binding of PBPs	Gram-negatives, *Pseudomonas* including KPC, AmpC, OXA-48 enzyme, and ESBL-producing organisms	2.5 g (2000 mg CAZ + 500 mg AVI) every 8 h	Abdominal pain, infusion-site reaction
Meropenem/vaborbactam	Carbapenem/BLI	Inhibits serine β-lactamases	Gram-negatives including ESBL and KPC Enterobacterales, AmpC β-lactamase–producing *P. aeruginosa*	4 g (2000 mg meropenem + 2000 mg vaborbactam) IV every 8 h	Infusion-site reactions, headache
Imipenem/relebactam	Carbapenem/BLI	Cell wall synthesis inhibitor combined with β-lactamase inhibitor	Gram-negatives, including Ambler class C, extended-spectrum β-lactamases, and *K. pneumoniae* carbapenemases	1.25 g (0.5 g imipenem + 0.5 g cilastatin + 0.25 g relebactam) IV every 6 h	Allergic reaction, neurotoxicity, diarrhea

ESBL, extended-spectrum β-lactamases; PBP, penicillin-binding protein; CRE, carbapenem-resistant Enterobacterales; MRSA, methicillin-resistant Staphylococcus aureus; MRCNS, methicillin-resistant coagulase-negative staphylococci; VRE, vancomycin-resistant enterococci; KPC, Klebsiella pneumoniae carbapenemase.

nonpseudomonal infection, it is best to switch to a single agent that the organism is sensitive to, using imipenem, meropenem, cefepime, piperacillin/tazobactam, a newer β-lactam/β-lactamase inhibitor combination, ciprofloxacin, or high-dose levofloxacin.

The drug of choice for *Acinetobacter* spp. is a carbapenem, but colistin should be considered with carbapenem resistance. Tigecycline monotherapy is not recommended, but this agent can be combined with a carbapenem, colistin, or sulbactam. Aerosolized aminoglycosides or colistin can be added as adjunctive therapy in patients with highly resistant Gram-negative pathogens.

The use of empiric combination therapy in VAP is controversial, and there are few data to suggest that use of an aminoglycoside with a β-lactam is more effective than β-lactam monotherapy. Dual therapy may have value if the patient is neutropenic or if pseudomonal bacteremia is present, but both situations are uncommon. Thus, the most compelling reason for using empiric combination therapy in patients with suspected MDR pathogens is to provide a broad enough spectrum of agents to increase the likelihood that the initial therapy is appropriate. Once the organism is identified, it is possible to de-escalate therapy. In patients with pneumonia and sepsis, dual adequate therapy is more effective than single effective therapy, possibly because of more rapid bacterial eradication.[120]

■ De-Escalation of Antibiotic Therapy for HAP/VAP

Antibiotic overuse causes bacterial resistance, which can in turn lead to inappropriate empiric therapy. To minimize this risk, it is necessary to de-escalate after an initial broad-spectrum therapy, which can involve using fewer drugs, drugs of a narrower spectrum, and short durations of therapy. Chastre et al., in a multicenter, randomized, controlled trial, demonstrated that patients who received appropriate initial empiric therapy of VAP for 8 days had outcomes similar to those patients who received therapy for 14 days.[121] Short-duration therapy was associated with a trend toward relapse if the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp. In another study, investigators prospectively randomized VAP patients to receive 15 days ($n = 109$) versus 8 days ($n = 116$) of therapy,[122] finding no difference in mortality, ICU length of stay, and mechanical ventilation days between both the groups. It is possible to effectively treat VAP with 6 to 8 days of therapy, provided that the initial therapy is appropriate.[4] The optimal duration of therapy for infections caused by *P. aeruginosa* and MRSA is still uncertain, but prolonged therapy may be no better than short duration therapy, in the absence of bacteremia.

In clinical studies of VAP, the rate of de-escalation has varied from 16% to 74%, with the highest rates being in those who are treated with a protocol for de-escalation, when initial therapy is appropriate, when initial cultures are positive (although it can be done with negative cultures), when the therapy involves broad-spectrum agents and multiple agents, and if the frequency of MDR pathogens is not high.[123] However, one recent study of 1495 ICU patients found that de-escalation was done in only 16% within the first 3 days, despite half getting empiric combination therapy and a quarter involving a carbapenem.[124] De-escalation does not appear to be dangerous and may be associated with reduced mortality, compared with no change in antibiotics. The decision to change antibiotics is made by assessing clinical features such as fever, leukocytosis, purulence of secretions, radiographic patterns, and oxygenation. In general, the best clinical predictor of response is improvement in oxygenation, which usually occurs by day 3 in survivors of VAP, but not in nonsurvivors. If the patient is improving, then cultures should be checked and efforts made to de-escalate and shorten duration of therapy. In some instances, all signs of pneumonia are gone by day 2 to 3, respiratory cultures are negative, and, in retrospect, the diagnosis was heart failure or atelectasis—and antibiotics can be completely stopped. Serial measurement of biomarkers such as procalcitonin (PCT) can help guide therapy discontinuation for VAP and help decrease the number of days on antibiotic, without having an adverse effect on mortality.[115,125] In several large studies, de-escalation guided by a PCT-based algorithm, primarily in ICU patients with HAP and CAP, has been safely done and led to reduced overall mortality due to fewer antibiotic-associated side effects.[126]

ANTIMICROBIAL STEWARDSHIP

Antimicrobial control or stewardship programs involve a number of interventions and require a committed champion and a good knowledge of local antibiotic usage patterns. The principles of antimicrobial stewardship have been compiled into a guideline, the focus of which is on prospective audit and feedback of antibiotic use, de-escalation of broad-spectrum therapy, proper dosing, and the development of local guidelines for antibiotic use based on knowledge of local microbiology.[59] Antibiotic restriction was not a highly recommended strategy, nor was restricting access to specific antibiotics.

CHAPTER 126

Viral Infections of the Lung and Respiratory Tract

John Treanor

GENERAL PRINCIPLES

Viral infections of the upper and lower airways have a major impact on health. Acute respiratory illnesses, caused largely by viruses, are the most common illness experience for otherwise healthy adults and children. Past data from the National Health Interview Survey suggested that such illnesses are experienced at a rate of 85.6 illnesses per 100 persons per year, and account for 54% of all acute conditions exclusive of injuries.[1] A total of 44% of these illnesses require medical attention and result in 287 days of restricted activity, 94.4 days lost from work, and 182 days lost from school per 100 persons per year. Estimates from family-based surveillance suggest that approximately one-fourth of these illnesses result in consultation with a physician. Illness rates for all acute respiratory conditions are highest in young children; children below the age of 9 are estimated to experience between 5 and 9 respiratory illnesses per year, whereas adults experience between 3 and 5 such illnesses.[2,3]

Mortality due to acute viral respiratory infection in otherwise healthy individuals in economically developed countries is relatively rare, with the exceptions of influenza and the recently emergent coronavirus. However, acute respiratory infection is a major cause of childhood mortality in developing countries, and it is estimated that 4.5 million children under 5 years of age die annually from acute respiratory infection.[4] Viruses are identified in about 3% to 40% of cases of respiratory disease in this setting and are estimated to play a contributing role in approximately 20% to 30% of deaths. In addition, new and emerging respiratory viruses such as hantavirus, emerging coronaviruses, and transmission of influenza viruses from avian or swine sources to humans pose a continuing threat.

Epidemiology

Many of the viruses associated with acute respiratory disease display a significant seasonal variation in incidence. Although the exact seasonal arrival of each virus in the community cannot be predicted with precision, certain generalizations are useful diagnostically and in planning control strategies. For example, influenza and respiratory syncytial virus epidemics both occur predominantly in the winter months, with a peak prevalence in January to March in the northern hemisphere. Parainfluenza virus type 3 (PIV-3) infections show a predominance in the spring, whereas types 1 and 2 (PIV-1 and PIV-2) cause outbreaks in the fall to early winter. Rhinoviruses may be isolated throughout the year, with increases in frequency in the spring and fall. The peak prevalence of enteroviral isolations is in late summer and early fall, whereas adenoviruses are isolated at roughly equal rates throughout the year. The herpes viruses also do not show significant seasonal variation in incidence, except for varicella, which occurs throughout the year but more commonly in late winter and early spring.

The reasons for these seasonal changes are not entirely clear. One mechanism may involve seasonal effects on virus transmissibility either because of more favorable environmental conditions for virus survival[5] or because of behavioral changes that increase transmission, such as indoor crowding. Effects of season on host susceptibility or response to infection also could play a role. All these factors could determine the eventual seasonal pattern of SARS-CoV-2.

Characteristics of the Viruses

Viruses of importance in the respiratory tract include both those considered to be principal respiratory viruses, whose replication is generally restricted to the respiratory tract, and others in which respiratory involvement is part of a generalized infection. The classification of these viruses depends in part on the type and configuration of the nucleic acid in the viral genome, the characteristics of the viral structural proteins, and the presence or absence of a lipid-containing envelope surrounding the virus particle (Table 126-1). The number of distinct antigenic types in each of the virus families varies. For example, the adenovirus and rhinovirus groups are composed of large numbers of antigenically (i.e., serotypically) distinct immunotypes, but other groups, such as paramyxovirus and respiratory syncytial virus, are composed of only a limited number of immunotypes. The degree of antigenic stability of the virus is an important factor in determining frequency of reinfection. This characteristic is particularly important for influenza type A virus, which periodically undergoes both minor and major changes in its surface antigens.

Transmission

The routes by which the different respiratory viruses spread from person to person are still not established with certainty. Rhinovirus and respiratory syncytial virus spread, at least in part, by direct hand contact with contaminated skin and environmental surfaces. This is followed by self-inoculation of infectious virus onto the nasal mucosa or conjunctiva. Others, including influenza, measles, and varicella-zoster viruses, spread at times in small-particle aerosols. Many viruses may spread by means of large-particle aerosols over short distances (<1 m). The relative importance of the various transmission routes under natural conditions for each virus can be quite variable.[6]

Pathogenesis of Infection

The initial sites of infection and pathogenesis differ for the various virus groups. Some, such as rhinovirus, are associated mainly with upper respiratory tract involvement. Others, such as influenza and coronavirus, commonly invade the lower airways and sometimes pulmonary parenchyma in addition to causing upper airway disease. The viruses also differ in the amount of damage produced in the cells lining the respiratory tract. Extensive damage to the respiratory epithelium is a characteristic feature of influenza virus infection, but biopsy studies show little evidence of nasal epithelial damage in persons with rhinovirus colds. Instead, colds are related both to virus damage to the respiratory tract and to the host responses to infection, including immunologic events, release of mediators of inflammation, and neurogenic reflexes.

An additional important feature of respiratory virus infections is their effect on the resident bacterial flora of the upper airways. Respiratory virus infections have been found to alter bacterial colonization patterns, increase bacterial adhesion to respiratory epithelium, and reduce mucociliary clearance and phagocytosis.

TABLE 126-1 Common Respiratory Viruses

Virus	Family	Genome	Seasonality	Diseases	Vaccine	Antivirals
Influenza virus	Orthomyxoviridae	ss RNA (–)	Yes (Winter)	Influenza, croup, bronchitis, pneumonia	Yes	Yes (oseltamivir, zanamivir, pimodivir, baloxavir)
Respiratory syncytial virus (RSV)	Paramxyoviridae	ss RNA (–)	Yes (Winter)	Bronchiolitis, pneumonia	No	Yes (ribavirin is available but not routinely recommended)
Metapneumovirus (hMPV)	Paramxyoviridae	ss RNA (–)	Yes (Winter)	Bronchiolitis, pneumonia	No	No
Parainfluenza virus (PIV)	Paramyxoviridae	ss RNA (–)	Yes (Winter)	Croup (PIV1), pneumonia (PIV3)	No	No
Measles	Paramyxoviridae	ss RNA (–)	No	Croup, pneumonia	Yes	No
Rhinovirus	Picornaviridae	ss RNA (+)	Yes (Spring, Fall)	Common cold	No	No
Seasonal coronavirus (hCoV)	Coronaviridae	ss RNA (+)	Some (Winter)	Common cold (OC43), pneumonia (HuCoV)	No	Yes (interferon α?)
Pandemic coronavirus	Coronaviridae	Ss RNA (+) ss RNA	No	SARS (SARS-CoV) MERS (MERS-CoV) COVID-19 (SARS-CoV-2)	Yes	Yes (remdesivir, nirmatrelvir/ritonavir [Paxlovid], molnupiravir)
Sin Nombre virus	Bunyaviridae	ss RNA (+/–)	No	Pneumonia	No	No
Adenovirus	Adenoviridae	ds DNA	No	Croup, pneumonia	Yes	No
Herpes simplex	Herpesviridae	ds DNA	No	Pneumonia	No	Yes (acyclovir, famciclovir)
Varicella zoster virus	Herpesviridae	ds DNA	No	Pneumonia	Yes	Yes (acyclovir, famciclovir)
Cytomegalovirus	Herpesviridae	ds DNA	No	Pharyngitis, pneumonia	No	Yes (ganciclovir, cidofovir)
Epstein-Barr virus	Herpesviridae	ds DNA	No	Pharyngitis	No	No
Bocavirus	Parvoviridae	ss DNA (+/–)	No	Bronchiolitis, colds	No	No

These impairments of host defenses by virus allow colonization by pathogenic bacteria and invasion of normally sterile areas, such as the paranasal sinuses, middle ear, and lower respiratory tract, resulting in secondary infection.

A summary of the specific viral etiologies most commonly associated with syndromes of upper respiratory tract infection is given in Table 126-2. The following sections briefly summarize the important points of viral respiratory tract infections.

THE COMMON COLD

The clinical features of the extremely common upper respiratory tract infection known as the "common cold" are discussed below.

TABLE 126-2 Virus-associated Respiratory Tract Infections

Clinical Syndrome	Associated Viruses
Common cold	Rhinovirus, other picornaviruses, RSV, PIV, coronavirus, adenovirus
Pharyngitis	Rhinovirus, influenza, EBV, CMV, HSV, HIV
Tracheobronchitis	Influenza, adenovirus, rhinovirus
Croup	PIV1, PIV2, influenza, adenovirus, measles
Bronchiolitis	RSV, hMPV, HuCoV-NL63, bocavirus
Pneumonia	
Adults	Influenza, adenovirus, RSV, PIV, measles, VZV, Sin Nombre virus, CoV-SARS, CoV-MERS, CoV-SARS-2
Children	RSV, PIV, influenza, measles, adenovirus, rhinovirus, CMV
Immunocompromised	CMV, HSV, VZV, adenovirus, RNA viruses

Clinical Features

The term "cold" really does not constitute a single entity, but rather a group of similar illnesses of differing cause. However, all colds include symptoms of rhinitis with variable degrees of pharyngitis. Predominant associated symptoms include nasal stuffiness, sneezing, runny nose, and sore throat. Patients often report chills, but fever is not a typical feature of uncomplicated colds. Cough and hoarseness are variably present and may be more frequent in the elderly,[7] but other lower respiratory tract signs and symptoms are not typical of colds and should raise suspicion of other entities.

Physical findings are nonspecific and most commonly include nasal discharge and pharyngeal inflammation. More severe disease, with higher fever, may be seen in children. Although colds are generally self-limited, symptoms may last for a surprisingly long period of time, with a median duration of illness of approximately 9 to 10 days in adults.[8] Recognized complications of colds include secondary bacterial infections of the paranasal sinuses and middle ear, and exacerbations of asthma, chronic bronchitis, and emphysema. Colds are frequently associated with involvement of the middle ear, likely due to eustachian tube dysfunction. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults, and in a higher proportion in young children.

Colds are also associated with detectable abnormalities of the paranasal sinuses, which may or may not be evident clinically. Mucosal thickening and/or sinus exudates have been observed in as many as 77% of subjects with acute colds.[9] These abnormalities are transient and usually not associated with symptoms, although they may persist 21 days or longer. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults[10] and in a higher proportion in young children.[11] Rhinoviruses and other common cold viruses have been detected in middle ear fluids in approximately 20% to 40% of cases of otitis media with effusion in children.[12] Infections with RSV, influenza, and adenoviruses are often also associated with otitis media.[11] However, clinically manifest acute sinusitis is seen in a small (0.5%–5%) proportion of individuals with naturally occurring colds.

Clinical colds in atopic individuals may be more severe or more likely to result in wheezing than in normal individuals, and rhinoviruses have been identified as major causes of asthma exacerbations in children and adults.[13] Rhinovirus colds may increase asthma by augmenting airway allergic responses such as histamine release and eosinophil influx after antigen challenge. Rhinoviruses have also been identified as important causes of exacerbations of chronic obstructive pulmonary disease (COPD).[14,15]

Viral Etiologies and Differential Diagnosis

Epidemiologic studies have established that the great majority of common colds are associated with infection with the human rhinoviruses or other picornaviruses. Other agents frequently associated with common colds include seasonal coronaviruses, parainfluenza, and respiratory syncytial virus, with a variety of other agents implicated occasionally. The clinical characteristics of illness due to each of these viruses are similar, and a specific viral etiology generally cannot be deduced on clinical grounds alone. Epidemiologic studies have indicated that on an annual basis, any one antigenic type of virus is responsible for less than 1% of all colds.

The differential diagnosis of individuals presenting with typical signs and symptoms is not extensive. However, in the presence of additional signs or symptoms that are not part of this clinical description, such as high persistent fever, signs of respiratory distress, or lower respiratory tract disease, alternative diagnoses should be sought. Allergic causes should be considered in individuals who present with recurrent symptoms restricted to the upper respiratory tract.

Pathogenesis

Studies of the pathogenesis of the common cold have largely focused on rhinoviruses, which constitute the most commonly implicated viral etiology. In situ hybridization studies of nasal biopsy specimens from rhinovirus-infected subjects demonstrate that infection is largely confined to relatively small numbers of ciliated nasal mucosal epithelial cells , although occasional nonciliated cells are also infected.[16] Sloughing of these epithelial cells is seen in naturally occurring colds, but the epithelial lining remains intact, with structurally normal cell borders. Infection is associated with significant increases in the numbers of polymorphonuclear leukocytes in nasal mucosa and secretions, probably due to elaboration of IL-8 by infected cells.[17] Although rhinoviruses are not able to grow efficiently at body temperature, virus can be detected within cells of the lower airway even in uncomplicated colds in healthy subjects.[18]

In general, the number of infected cells appears to be quite limited, even in fairly symptomatic individuals, and there is no clear correlation between the level of virus replication or the number of cells infected, and the level of symptomatology. These results have suggested that virus-induced cellular injury is not the direct cause of symptoms in rhinovirus colds, but rather that inflammatory mediators play an important role. Analysis of the nature of the mucosal exudate during rhinovirus colds suggests that the nasal secretions during the initial response to rhinovirus infection are predominantly the result of increased vascular permeability, as demonstrated by elevated levels of plasma proteins in nasal secretions,[19] whereas later glandular secretions (lactoferrin, lysozyme, and secretory IgA) predominate. Similar observations have been made in allergic rhinitis. However, in contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds, as nasal histamine levels do not increase and therapy with selective H1 antihistamine is not effective.[20,21] Nasal secretion kinin levels do correlate with symptoms in natural and experimental colds, and intranasal administration of bradykinin mimics the induction of signs and symptoms in the common cold,[21,22] including increased nasal vascular permeability, rhinitis, and sore throat.

Diagnostic Tests

Molecular diagnostic tests have been developed for many of the viruses associated with the common cold. Since there is no specific therapy and the clinical characteristics of colds due to different viruses are similar, use of techniques for specific viral diagnosis in the common cold is generally limited to the research setting.

Treatment and Prevention

The recommended treatment for colds is to use individual remedies to treat specific symptoms. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective sedating antihistamines,[23,24] although a recent meta-analysis suggested only short-term benefit.[25] Studies of pseudoephedrine have demonstrated measurable improvements in nasal air flow consistent with a decongestant effect. In previously healthy children and adults, there is no danger from the routine use of cough suppressants, although they should be used cautiously in patients with serious underlying COPD. Cough syrups containing expectorants are of unproved value in common colds, although guaifenesin may reduce the cough reflex.

Symptomatic therapy with systemic anticholinergic drugs or anticholinergic–sympathomimetic combinations has not been shown to confer any benefit, and is associated with significant side effects, especially in children.[26,27] In addition, the use of the decongestant phenylpropanolamine is associated with an increased risk of hemorrhagic stroke,[18,28] and this drug has been removed from over-the-counter cold remedies.

Topical application of vasoconstrictors such as phenylephrine or ephedrine provides relief of nasal obstruction but may be associated with a rebound of symptoms upon discontinuation if used for more than a few days. Thus, nasal sprays containing decongestants should be used for no more than 3 days. Topical application of ipratropium, a quaternary anticholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds.[29] This agent probably exerts its major effect on the parasympathetic regulation of mucous and seromucous glands. Over-the-counter use of oral zinc for treatment of common colds has not been associated with significant efficacy.[30] It has also not been possible to demonstrate substantial benefit of *Echinacea*, an herbal remedy based on the purple coneflower for either treatment or prevention of colds.[31]

There has been considerable interest in the development of antiviral agents for the common cold. Several problems confront the successful development of such an antiviral agent. Because of the numerous etiologic agents, the ideal drug would require a wide spectrum of activity. In addition, many drugs that appear to have excellent in vitro activity have failed in clinical trials, apparently because they did not reach sufficient levels within the nasal mucosa where virus replication occurs. Finally, because symptoms in colds are not clearly related to the level of virus replication, a successful treatment strategy may also require use of drugs to antagonize the effects of inflammatory mediators.[32]

LARYNGITIS AND PHARYNGITIS

The viral etiologies and clinical manifestations of laryngitis and pharyngitis are considered below.

Clinical Features

Pharyngitis is a common complaint of both adults and children and is one of the most common reasons for seeking outpatient medical care. In general, this syndrome refers to individuals who present with the primary complaint of sore throat and should probably be reserved for those individuals who manifest some objective evidence of pharyngeal inflammation as well. The clinical manifestations of pharyngitis are dominated by the specific causative agent. However, generally the syndrome can be divided into those cases in which nasal symptoms accompany pharyngitis, which are predominantly viral in nature, and those cases without nasal symptoms, which have a somewhat more diverse spectrum of etiologic considerations, including both group A and nongroup A streptococci, *Chlamydia* (strain TWAR), *Mycoplasma*, and other agents.[33]

Viral Etiologies and Differential Diagnosis

Rhinovirus colds are frequently accompanied by pharyngitis, although objective signs of pharyngeal inflammation are uncommon. Adenovirus infections are frequently associated with pharyngitis, and a specific syndrome of pharyngoconjunctival fever, consisting of fever, pharyngitis, and bilateral conjunctivitis is associated with adenovirus types 3 and 7. A variety of enteroviral serotypes are associated with febrile pharyngitis. Herpangina is a specific Coxsackie virus–induced pharyngitis in which small (1- to 2-mm) vesicular lesions of the soft palate rupture to become small white ulcers. Pharyngitis is a typical component of acute influenza in which individuals experience the sudden onset of systemic symptoms of fever, myalgias, and malaise accompanied by upper respiratory signs and symptoms, including pharyngitis. Primary oral infection with herpes simplex virus may present with pharyngitis, typically with vesicles and shallow ulcers of the palate, and cervical lymphadenopathy.

Pharyngitis may be the presenting or predominating symptom in more generalized viral infections. Pharyngitis is a significant complaint in approximately one-half of cases of the acute mononucleosis syndrome due to Epstein-Barr virus. Pharyngitis in this syndrome is generally exudative and can be accompanied by cervical and generalized lymphadenopathy, as well as fever, hepatosplenomegaly, and other systemic symptoms. The heterophile antibody test (Monospot) is typically positive in the second week of illness. Cytomegalovirus can cause an identical syndrome that is Monospot negative. Cytomegalovirus may be associated with pharyngitis more commonly in children than in adults. An acute mononucleosis-like syndrome with pharyngitis may also be the presenting manifestation of primary HIV infection and toxoplasmosis. Viruses in the hemorrhagic fever group produce an acute pharyngitis that occurs early in the disease, before skin lesions appear. Also, exudative pharyngitis is a common clinical manifestation in Lassa fever.

The differential diagnosis of acute pharyngitis generally centers upon the differentiation of streptococcal from viral etiologies. Features suggestive of streptococcal pharyngitis include tonsillar swelling, moderate to severe tenderness on palpation, enlargement of lymph nodes, presence of scarlatiniform rash, and absence of coryza. The presence of nasal symptoms or of conjunctivitis favors a viral etiology, and as described, some viral syndromes may present with distinguishing characteristics that help in their identification. Generally, acute pharyngitis in children less than 3 years of age is predominantly viral in origin. The presence of exudate is suggestive of bacterial etiology, but exudates may also be seen with adenovirus or Epstein-Barr virus.

Pathogenesis

As described, pharyngitis in the common cold is probably the result of chemical mediators of inflammation, which are potent stimulators of pain nerve endings. Potentially similar mechanisms may account for pharyngitis in other viral syndromes as well. Direct viral damage and other host inflammatory responses also may contribute. Pharyngitis occurs most often as part of the common cold syndrome and thus is usually associated with the same viruses that cause colds. In some cases, pharyngeal symptoms predominate to a degree that overshadows other complaints. The kinins are potent stimulators of pain nerve endings, and high levels of bradykinin and lysyl bradykinin are present in nasal secretions of patients with rhinovirus colds. Intranasal application of bradykinin promotes sore throat and nasal symptoms in volunteers, supporting a role for these agents in the pathogenesis of cold symptoms.

Diagnostic Tests

Rapid antigen detection tests are available for respiratory syncytial virus and influenza A virus. Rapid diagnostic tests are widely available for the office identification of group A streptococci and are indicated in most cases in which the etiology is uncertain. When highly sensitive tests are used, backup cultures are generally not necessary. Routine studies for other bacterial and nonbacterial pathogens are usually not obtained. Identification of viral causes of pharyngitis is generally possible through isolation in cell culture but is seldom attempted in clinical practice. Use of guideline recommendations for the selective use of throat cultures combined with antibiotic treatment based only on positive rapid test or throat culture can reduce unnecessary use of antibiotics for treatment of pharyngitis.[34]

Treatment and Prevention

The treatment of most cases of viral pharyngitis is symptomatic, as noted in the section on common colds. Patients suspected of having influenza pharyngitis who are seen within the first 2 days of illness can be treated with antiviral therapy (see “Influenza Virus,” below). In immunosuppressed patients with chronic herpetic pharyngitis or normal hosts with primary gingivostomatitis, acyclovir therapy is recommended (see “Herpes Simplex Virus,” below).

Treatment of group A streptococcal infections with antimicrobial agents is generally initiated to prevent rheumatologic complications of this infection, and because treatment of acute streptococcal pharyngitis is associated with more rapid resolution of symptoms,[35] although the absolute benefits are rather modest.

CROUP

Croup represents an important clinical entity, especially in children, as discussed below.

Clinical Features

Croup, or viral laryngotracheobronchitis, is a clinically distinct illness that predominantly affects children under the age of 3. The illness typically begins with upper respiratory tract symptoms of rhinorrhea and sore throat, often with a mild cough. After 2 or 3 days, the cough deepens and develops a characteristic brassy, barking quality, which is similar to a seal’s bark. Fever between 38°C and 40°C is common, although those with croup due to respiratory syncytial virus may have normal temperatures. The child may appear apprehensive and most comfortable sitting forward in bed. The respiratory rate is elevated, but usually not over 50; this contrasts with bronchiolitis, in which more severe tachypnea is often seen. Chest wall retractions, particularly in the supraclavicular and suprasternal areas, may be observed. Children with this finding on presentation have a higher risk of hospitalization or of requiring ventilatory support.

The characteristic physical finding of croup is inspiratory stridor. Inspiration is prolonged, and in very severe cases, some degree of expiratory obstruction also may be seen. Rales, rhonchi, and wheezing, which reflect the characteristic involvement of the lower respiratory tract, may be heard on physical examination. A fluctuating course is typical for viral croup, and the child may appear to worsen or improve within an hour. The typical duration of croup is 3 to 4 days.

Hypoxemia occurs in 80% of children with croup severe enough to require hospitalization. The degree of hypoxia is generally difficult to ascertain clinically, but pulse oximetry provides a reliable and noninvasive means to monitor the state of oxygenation. Children who develop respiratory insufficiency as a result of increasing fatigue may also have elevations of Pa_{CO_2}.

Children with croup characteristically exhibit subglottic narrowing of the tracheal air shadow on PA films of the neck, the "steeple" sign. This finding may be useful in differentiating croup from epiglottitis. However, radiographs are limited in accuracy, and when the diagnosis is uncertain, radiologic and pharyngeal examination should be avoided because of the risk of cardiorespiratory arrest in acute epiglottitis. Emergency assessment by an otolaryngologist or an anesthesiologist is indicated in this situation. Chest x-rays may reveal parenchymal infiltrates, which are part of the characteristic involvement of the lower respiratory tract in this syndrome.

■ Viral Etiologies and Differential Diagnosis

Parainfluenza viruses type 1 and 2 are the most common viruses responsible for croup, accounting for about 75% of cases,[36] and the seasonal incidence of croup reflects the seasonal variations in parainfluenza virus incidence. Less common causes of croup include respiratory syncytial virus, influenza A or B viruses, measles, rhinoviruses, and adenoviruses as well as *Mycoplasma pneumoniae.* Parainfluenza virus type 2, influenza A viruses, and measles are associated with more severe disease, but generally, the clinical presentation of the croup syndrome due to individual agents is similar.

The majority of cases of inspiratory stridor in children are caused by viral croup. However, it is critical to distinguish these syndromes from other, potentially more serious causes of airway obstruction such as bacterial epiglottitis and tracheitis early in clinical management. Epiglottitis is an acute cellulitis of the epiglottis and surrounding structures. Patients present with acute respiratory distress and drooling, but the barking cough of croup is absent. Since the introduction of effective vaccines for the major bacterial cause or epiglottitis, *Haemophilus influenzae* type b (Hib), the incidence of epiglottitis in children has also declined considerably. In adults, and rarely in children, epiglottitis may be caused by a variety of other bacterial agents such as *Haemophilus parainfluenzae* or α-hemolytic streptococci, which may spread from a contiguous focus of infection. Bacterial tracheitis is a relatively rare syndrome that mimics croup. Abundant purulent sputum is often present. Bacterial tracheitis is usually caused by *Staphylococcus aureus* or Hib; other bacteria such as *Streptococcus pneumoniae* also have been associated with this syndrome. Other infectious causes of stridor, including peritonsillar or retropharyngeal abscess, or diphtheria, should be considered. Evidence of noninfectious causes of stridor, such as trauma or aspiration of a foreign body, also should be sought in the history and physical examination.

■ Pathogenesis

The severity of clinical symptoms in parainfluenza virus croup appears to be directly related to the level of virus replication.[37] The viral infection in croup produces inflammation both in the upper respiratory tract and in the lung parenchyma. The classic signs of croup, including barking cough and inspiratory stridor, arise mostly from inflammation occurring in the larynx and trachea. Inflammatory changes are seen by histology in the epithelial mucosa and submucosa of the larynx and trachea. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes. The inflammation and obstruction are greatest at the subglottic level, which is the least distensible part of the airway because it is encircled by the cricoid cartilage. Consequently, localized inflammation and edema lead to obstruction of airflow. The impeded flow of air through this narrowed area produces the classic high-pitched vibration. Obstruction is greater during inspiration because it occurs in the extrathoracic portion of the airway and is enhanced in small children because the walls of the airways in these individuals are relatively compliant. Obstruction of airflow results in an initial decline in tidal volume, which is compensated by an increase in respiratory rate to maintain adequate alveolar ventilation. However, if the obstruction increases, the work of breathing may increase until the child tires, and as the respiratory rate declines, the child develops hypercarbia and respiratory failure.

Involvement of the lower respiratory tract with resulting hypoxia is integral to the pathophysiology of croup.[38] Inflammatory changes are noted throughout the respiratory tract, including the linings of the bronchi, bronchioles, and even the alveoli. Although some degree of hypoxia can be explained on the basis of hypercarbia, the major pathophysiologic mechanism is ventilation–perfusion mismatching.

Pulmonary edema may complicate severe croup and upper airway obstruction. The onset of pulmonary edema often is immediately following intubation. Pulmonary edema in these cases does not appear to be due to pulmonary artery hypertension, but to local hypoxia and increased alveolar–capillary transmural pressure.

In addition to these anatomic pathophysiologic events, immunologic mechanisms also may play a role in some manifestations or in determining the severity of disease. Virus-specific IgE responses appear earlier and are of greater magnitude in patients with parainfluenza virus-associated croup than in age-matched controls with simple upper respiratory illness. Histamine is also detectable in upper respiratory tract secretions in this condition. There also appears to be a relationship between croup and subsequent reactive airways disease.[39]

■ Diagnostic Tests

Parainfluenza viruses and other viruses associated with croup can be isolated in cell culture, and specific viral diagnosis can be made by PCR, but the clinical syndrome is sufficient for diagnosis, and management generally does not depend on identification of the specific agent.

■ Treatment and Prevention

Because most hospitalized children are hypoxic, oxygen is the mainstay of treatment for severe disease and should be given to all hypoxemic patients. Use of helium as the carrying gas, rather than air, has been suggested as a method to decrease the work of breathing. However, this approach requires use of 70% helium to be effective and limits the amount of oxygen that can be delivered.[40] Humidified air or mist therapy is commonly used and has several potential roles. Desiccation of the inflamed epithelial surfaces is decreased, and the viscosity of the exudate is reduced. However, the value of mist therapy has not been proven, and it should be recognized that water from the standard home-use vaporizer cannot reach the lower respiratory tract because of the large particle size. In addition, removal of the child from the parents and placement in a mist tent can be more distressing to the child than beneficial.

Administration of nebulized racemic epinephrine generally gives rapid, symptomatic relief in croup.[41] It is believed that α-adrenergic stimulation by this drug causes mucosal vasoconstriction, leading to decreased subglottic edema. Several randomized trials have demonstrated a rapid beneficial effect on airway obstruction.[42,43] The onset of action is rapid, often within minutes, but the duration of relief also is limited, lasting 2 h or less. Therefore, treated subjects should be observed closely for clinical deterioration. Although symptomatic relief is considerable, use of epinephrine is not associated with improvements in oxygenation, probably because the defect in oxygen is associated with ventilation–perfusion mismatching due to lower respiratory tract involvement. In addition, tachycardia may occur. Thus, inhaled epinephrine is generally reserved for children who fail to respond to more conservative management,[44] although some centers use it routinely.

Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup,[45] including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of intramuscular, oral, or nebulized steroids appears to be equally effective,[46,47] and low-dose dexamethasone or prednisolone equally effective as standard dose.[48] Administration of single-dose steroid therapy in this setting has not been associated with significant side effects[49] and should probably be used in any patient with illness significant enough to require an emergency room or clinic visit.

Antiviral agents effective against some of the viruses responsible for croup are available but have not been tested for efficacy in this situation. However, the potential benefit of the use of antiviral agents in the typical self-limited course of croup would likely be limited. Since croup is a viral illness, antibiotic therapy is of no benefit. Vaccines are currently available for both measles and influenza, but there are currently no vaccines available for parainfluenza virus.

TRACHEOBRONCHITIS

Tracheobronchitis is an extremely common disorder with diverse etiologies.

Clinical Features

In addition to causing croup and bronchiolitis, viral infection of the trachea and bronchi may cause tracheitis or tracheobronchitis. The diagnosis of acute bronchitis is usually applied to cases of acute respiratory disease with severe and prolonged cough that continues after other signs and symptoms of the acute infection have subsided. Cough occurs during the first week of illness in 30% of rhinovirus colds in young adults and in 80% or more of cases of influenza A virus infection, in which it is often prolonged. Adenovirus infections characteristically involve the tracheobronchial tree, with resultant bronchitis that in military populations is part of the syndrome of acute respiratory disease. Tracheitis is characterized by tracheal tenderness, which can be elicited by gentle pressure on the anterior trachea just below the cricoid cartilage. Substernal discomfort on inhalation, and nonproductive paroxysmal cough, are noted. Paroxysmal nonproductive cough also is characteristic of tracheobronchitis and is usually much more severe at night. Later in the course of illness, small amounts of clear or whitish sputum may be produced. Accompanying symptoms may include fever, headache, myalgias, malaise, and anorexia. After several days of coughing, chest wall or abdominal discomfort that is muscular in nature may be noted. Physical findings are generally nonspecific; examination of the chest may reveal no adventitious sounds, but more commonly diffuse rhonchi and occasional wheezing. Physical signs such as egophony, pleural friction rubs, or areas of dullness to percussion are not present.

Pathogenesis

The mechanisms of cough production in viral infection are not well understood but may include direct damage to the respiratory mucosa, release of inflammatory substances in response to the infection, increased production and/or decreased clearance of respiratory secretions, and stimulation of airway irritant receptors. Intranasal application of several prostaglandins also produces cough in uninfected volunteers.[50] Infection may also enhance airway reactivity, leading to increased sensitivity to cold air and pollutants such as smoke.

Viral Etiologies and Differential Diagnosis

Tracheobronchitis is most typically caused by influenza A or B virus. In adults, other common respiratory viruses such as parainfluenza virus or respiratory syncytial virus may present with prolonged cough. Herpes simplex has been associated with necrotizing tracheobronchitis in nonimmunocompromised hosts. This syndrome is often accompanied by refractory bronchospasm.

The differential diagnosis of acute bronchitis includes nonviral infections and noninfectious etiologies such as cough-variant asthma. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infections cause prolonged cough. *Bordetella pertussis* infection also should be considered in the differential diagnosis. In otherwise healthy persons, workup of acute cough should be directed toward determining whether pneumonia is present, which would be more clinically concerning.

Diagnostic Tests

Many of the viral pathogens associated with tracheobronchitis can be detected in multiplexed nucleic acid–based diagnostics, but specific viral diagnosis is generally not necessary for appropriate management.

Treatment and Prevention

Treatment in adults is best effected by prescribing rest, aspirin for headache and fever, cold water vapor inhalation, and a cough syrup such as guaifenesin with dextromethorphan. For children, a cough suppressant may be helpful. In the absence of signs of pneumonia, treatment of prolonged cough with antibacterial agents is of no benefit and not recommended.[51,52]

BRONCHIOLITIS

Bronchiolitis is an important entity with significant clinical manifestations, the hallmark of which is airflow obstruction.

Clinical Features

Bronchiolitis is a fairly characteristic syndrome whose presenting symptoms are dominated by the major pathophysiologic defect, obstruction to expiratory air flow.[53] The onset of lower respiratory symptoms is usually preceded by rhinitis, often with nasal congestion and discharge. More severe symptoms characteristically occur 2 to 3 days later but in some cases are concurrent with the onset of upper respiratory symptoms.

The hallmark of disease is wheezing, which can be quite marked, with flaring of the nostrils and use of accessory muscles of respiration. Cough may or may not be prominent initially, and when cough is present, it may be paroxysmal in nature. Bronchiolitis may be complicated by apnea as well.[54] Slight cyanosis is often observed, but the presence or absence of cyanosis is not a reliable indicator of the degree of oxygenation or of the severity of disease. Physical findings are generally confined to the chest, with development of rales, which are usually musical in the beginning and then become moister. Hyperresonance of the chest may be observed, and the liver may be displaced downward. The respiratory rate is elevated, with rates of 50 to 80 breaths per min. Fever is frequently present at the beginning of the illness but may no longer be present at the time lower respiratory tract involvement develops. Among hospitalized infants, one-third or more are afebrile but have marked lower respiratory tract disease. Thus, the presence or absence of fever does not indicate the severity of the child's illness. Mild conjunctivitis is noted in about one-third of cases, with pharyngitis of varied severity in about one-half, and otitis media in 5% to 10%. The hospital course is variable, but most infants show improvement in 3 to 4 days.[55]

Radiologic findings are generally nonspecific, with reported findings including air trapping, consolidation, and collapse.[56] However, there is no correlation between the chest x-ray findings and the clinical course,[57] and in general, chest x-rays are not necessary in the evaluation of bronchiolitis.[58] Results of routine laboratory tests are generally unremarkable. Electrolyte disturbances, most notably hyponatremia, may be seen with severe disease, particularly if excessive amounts of hypotonic fluid are administered. Acute disease may be associated with elevations in pulmonary artery pressure, but echocardiographic studies are usually unremarkable in infants with structurally normal hearts.

Bronchiolitis is a disease predominantly of infancy, and the peak age incidence is between 2 and 6 months of age, with more than 80% of cases occurring in the first year of life. The risk of hospitalization and severe bronchiolitis is particularly high in infants with congenital heart disease, chronic lung disease, or immunodeficiency. In addition, infants born prematurely, and those who are less than 6 weeks of age at the time of presentation, also are at increased risk of hospitalization. More severe disease has also been documented in children with a family history of asthma, and in those exposed to cigarette smoke in the family setting.

Viral Etiologies and Differential Diagnosis

Respiratory syncytial virus (RSV) causes most cases of bronchiolitis. During the RSV season, essentially all cases are due to this virus. In the northern hemisphere, RSV season usually ranges from October to May, with a peak number of cases in December through February. Overall, RSV is recovered from about three-fourths of all infants admitted to the hospital with bronchiolitis.[53] Several other respiratory viruses are associated with bronchiolitis, including parainfluenza viruses, influenza virus, mumps, and rhinoviruses, and coinfections are common.[59]

The epidemiology and pathophysiology of parainfluenza bronchiolitis are similar to those of RSV, and particularly severe disease may be associated with parainfluenza virus type 3. Adenoviruses types 3, 7, and 21 are relatively uncommon causes but may be associated with more severe disease, including the development of bronchiolitis obliterans. Rhinoviruses represent a small but significant proportion of cases of bronchiolitis[60] and may mimic RSV infection in infants with bronchopulmonary dysplasia. Rhinoviruses and *Mycoplasma pneumoniae* become more important causes of infection-induced wheezing as children become older. Surveys of bronchiolitis in various parts of the world have suggested a similar pattern of viral etiologies.

A significant number of cases are associated with the human metapneumovirus (hMPV).[61] The clinical picture most closely resembles that of RSV, and bronchiolitis is the major manifestation in children. Clinical features include wheezing and hypoxia. There are no clinical features that can distinguish between disease caused by hMPV and RSV, although generally those due to RSV may be more severe. Seasonal human coronaviruses also have been associated with lower respiratory tract disease in infants.[62] Human bocavirus, a human parvovirus, has been found in as many as 20% of cases of acute wheezing in young children, often in conjunction with other viruses. The exact role it plays in this syndrome has not been determined completely.[63]

The differential diagnosis of diseases characterized by expiratory airflow obstruction in infants is relatively small. Pertussis can occasionally be confused with bronchiolitis; however, more frequent vomiting and more paroxysmal cough would be clues to the diagnosis. Anatomic defects such as vascular rings can cause obstruction of the airway. Foreign bodies should be considered strongly, especially in young infants. Gastroesophageal reflux is an additional consideration. The major differential diagnostic consideration is asthma, which is uncommon under the age of 1 year.

Pathogenesis

The pathophysiology of infectious bronchiolitis has been described most completely in the case of infection with RSV.[53] The average incubation period is 4 to 5 days, with a range of 2 to 8 days. Virus replication is limited to the respiratory tract mucosa, which may be involved through its entire length. Involvement of the lower respiratory tract probably occurs by cell-to-cell spread through the respiratory epithelium or aspiration of upper respiratory secretions. Pathologic findings in RSV bronchiolitis include necrosis of bronchiolar epithelium, loss of ciliated epithelial cells, and marked peribronchiolar mononuclear inflammation. Virus-induced cytopathology and associated submucosal edema leads to obstruction of smaller bronchioles, particularly in infants, with distal collapse or air-trapping.

Viral infection of epithelial cells of the bronchioles leads to destruction and necrosis of the ciliated epithelium. Lymphocytes can be seen in increased numbers in the peribronchial tissues. The submucosa becomes edematous, and there is increased production of mucus. Ultimately, dense plugs of alveolar debris and strands of fibrin form within small bronchi and bronchioles, which may partially or completely obstruct airflow. The pathogenic basis for respiratory difficulty in bronchiolitis is related to obstruction of these small airways. Hypoxemia is the major abnormality of gas exchange, with ventilation–perfusion imbalance the major cause of the hypoxemia. In addition to hypoxia, hypercarbia and respiratory acidosis have been observed in some severely ill infants.

Infants are particularly susceptible to the consequences of viral infection for several reasons. The peripheral airways are disproportionately narrow in the early years of life. In addition, collateral channels of ventilation, such as the pores of Kohn, are deficient in both number and size in the infant lung. Finally, the airways of infants are intrinsically more reactive to bronchospastic stimuli than are the airways of older children.[64]

The possibility that immune responses are involved in the pathogenesis of RSV bronchiolitis has received considerable attention. The presence of preexisting infection-induced antibody does not appear to play a role in enhancing the severity of disease because maternal antibody, or passively transferred antibody, is protective. It has also been postulated that cellular immune responses may be involved in the pathogenesis, since infants infected with RSV who have clinical bronchiolitis have higher levels of cell-mediated immunity to RSV than those with uncomplicated upper respiratory tract disease. Immediate hypersensitivity type reactions also have been postulated to play a role in the pathogenesis of wheezing in bronchiolitis. Production of virus-specific IgE and subsequent release of mediators of bronchoconstriction have been documented with RSV and PIV bronchiolitis. Leukotriene C4, a potent stimulant of airway smooth muscle constriction and mucus secretion, also is released into the airway in acute bronchiolitis.[65] Elevated levels of histamine and prostaglandin $F_2\alpha$ metabolite have been found during acute bronchiolitis and increased levels of eosinophilic cationic protein in nasopharyngeal secretions, suggesting that release of chemical mediators of inflammation in response to viral antigens is one factor contributing to the development of severe bronchiolitis.

The innate immune response also plays an important role in the pathogenesis of RSV disease in infants, and it has been recognized that single-nucleotide polymorphisms in several genes that control the inflammatory response have an important impact on the severity of RSV disease.[66] Examples include polymorphisms in the genes for IL-4, IL-8, and IL-13, and in TLR-4 and the CCR5 receptor, among others.

Following recovery from acute bronchiolitis, some children experience continued episodes of wheezing, especially during viral upper respiratory infections. Estimates are that 5% to 50% of children diagnosed as having bronchiolitis in infancy go on to develop recurrent episodes of wheezing. Generally wheezing episodes wane in frequency over the next several years. After clinical bronchiolitis, some individuals may also demonstrate increased bronchial responsiveness to histamine or cold challenge, which generally decreases over time. The mechanism by which RSV or other viral infection might lead to increased episodes of wheezing is unclear. Some individuals develop elevated levels of viral specific IgE, which may play a role in triggering bronchospasm upon re-exposure. In some studies, persistent wheezing correlates with a family history of asthma and with higher levels of IgE.

■ Diagnostic Tests

Specific viral diagnosis is possible by either detection of viral antigens or viral nucleic acid in nasopharyngeal secretions. However, routine virologic testing in bronchiolitis is not recommended because it does not impact management.[58] In transplant patients with suspected RSV pneumonia, samples of the lower respiratory tract by bronchoalveolar lavage are more sensitive than throat swabs for detection of RSV.

■ Treatment and Prevention

Recommendations regarding the treatment and prophylaxis of bronchiolitis have been summarized recently.[58] Oxygenation should be monitored by pulse oximetry, and oxygen administered to infants whose oxygen saturation consistently falls below 90%. Since bronchiolitis is a viral disease that is infrequently complicated by bacterial superinfection, routine treatment with antibiotics is not warranted. Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often needed, but care must be taken to avoid inducing hyponatremia. Fluid intake and electrolyte concentrations should be carefully monitored in all infants with severe bronchiolitis, as hyponatremia and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may occur.

There is general agreement that bronchodilators should not be administered to children with bronchiolitis. While bronchodilators may produce modest short-term improvements in clinical scores, t do not improve oxygenation, rates of hospitalization, or duration of hospital stay.[67–69] In addition, bronchodilating drugs may contribute to increased restlessness and cardiovascular stress. Because some children do respond to these drugs,[70] a reasonable strategy is a short trial of nebulized bronchodilator with continued therapy only in selected children who respond.

The majority of studies of systemic corticosteroids have also failed to demonstrate a beneficial effect in acute bronchiolitis.[71,72] A recent meta-analysis has shown that systemic steroids do not decrease admission rates.[73] Randomized trials of inhaled steroids also have not shown significant benefit in bronchiolitis.[74]

Ribavirin (1-β-D-ribofuranosyl-1,2,3-triazole-3-carboxamide) is a broad-spectrum antiviral agent with antiviral activity against multiple respiratory viruses including RSV in a variety of cell culture systems and animal models. It does not achieve suitable levels in respiratory secretions when administered systemically, so aerosolized drug has been used for treatment of bronchiolitis. Although initial randomized placebo-controlled trials of ribavirin given as a small-particle aerosol showed benefit in treatment of bronchiolitis, subsequent experience with use of the drug in clinical practice did not confirm this clinical benefit. The primary use of ribavirin currently is in treatment of RSV pneumonia in immunocompromised patients.[75] Multiple additional antivirals directed at RSV are in clinical development, but none is currently licensed. A common problem with these agents has been the rapid selection of resistant mutants, suggesting that multidrug approaches may be necessary.[76]

Bronchiolitis due to RSV can be prevented by passive transfer of antibody against this agent. A humanized neutralizing monoclonal antibody to the RSV F protein, palivizumab has significant protective efficacy in a population of infants with prematurity or bronchopulmonary dysplasia, as well as in children with hemodynamically significant congenital heart disease. Current recommendations for the use of passive antibody prophylaxis are to consider use in infants born before 29 weeks of gestation (who would be expected to receive little placental transfer of maternal antibody), and infants with hemodynamically significant heart disease or chronic lung disease of prematurity. Infants born before 29 weeks who will be less than 12 months during the subsequent RSV season should receive up to 5 monthly doses or until the end of the season, whichever comes first.[58] Palivizumab in not recommended for use in the second year of life or beyond, except for some cases of chronic lung disease of infancy. Palivizumab is not effective for therapy of RSV disease.[77]

Vaccines are available to prevent bronchiolitis due to influenza virus and mumps, but there is no vaccine currently available for prevention of bronchiolitis due to RSV. There are multiple significant hurdles to the development of such a vaccine, including the very young age at which the disease presents, the suppressive effect of maternal antibody on vaccine responses, and the potential for enhanced disease in vaccine recipients.[78]

VIRAL PNEUMONIA

Viral pneumonia is an extremely important clinical entity that affects a wide variety of hosts, both immunologically intact and immunologically compromised.

■ Clinical Features

Although there can be considerable variety to the presentation of viral pneumonia depending on the age and immunologic competence of the host, and the specific viral pathogen, there are certain general features that are described in the following.

Viral pneumonia in adults is usually associated with nonproductive cough, although production of frothy, pink-tinged sputum is seen in some severely ill individuals. Cyanosis and hypoxemia are prominent features of severe primary viral pneumonia. Physical findings are often nonspecific. The patient may appear acutely ill, conjunctivitis and rhinitis may be noted, and the trachea may be somewhat tender if accompanied by viral tracheitis. There is an increased respiratory rate, and diffuse rales and wheezes. A variety of chest x-ray patterns have been described, including lobar infiltrates, but most typically primary viral pneumonia presents with diffuse, bilateral interstitial infiltrates. However, there are really no x-ray patterns that reliably differentiate between bacterial and viral pneumonia. The sputum is relatively scant, it generally shows few polymorphonuclear leukocytes, and gram stain reveals minimal numbers of bacteria.

The basic presentation of viral pneumonia in children is similar. The clinical presentation varies considerably with the specific causative agent but typically includes fever and lower respiratory tract signs and symptoms, such as difficulty breathing, nonproductive cough, and physical findings of wheezing or increased breath sounds. Young infants may present with apneic episodes with minimal fever. The clinical presentation may be dominated by the associated croup or bronchiolitis, which are frequently present.

Underlying cardiopulmonary diseases, such as valvular heart disease or COPD, are well-recognized risk factors for viral pneumonia in adults and children. Pregnancy, particularly in the second and the third trimester, has been recognized as a risk factor for cardiopulmonary hospitalizations associated with influenza epidemics.

Bacterial superinfection is a common complication of viral lower respiratory tract infection, particularly in influenza. The classic presentation is that of a typical episode of viral illness with more or less complete recovery, followed 2 to 14 days later by a recurrence of fever and development of cough and dyspnea.[79] CXR reveals lobar infiltrates, and the clinical course is typical of bacterial pneumonia. In addition, combined bacterial and viral pneumonia, with clinical features of each, can occur in adults and with certain viruses in children.

Pathogenesis

The pathogenesis of viral infections of the lower respiratory tract can conveniently be considered in terms of infections initiated in and primarily confined to the respiratory tract, or so-called primary viral pneumonia, such as with influenza or RSV; processes in which infection is initiated in the respiratory tract with subsequent systemic manifestations, such as in measles or varicella; and processes in which respiratory tract involvement is secondary to a systemic infection, such as with CMV. Each of these situations may lead to what is recognized clinically as a viral pneumonia. In this discussion, the general features of primary viral pneumonia are discussed using influenza as a model, and pathogenesis of other forms of viral pneumonia is discussed briefly in comparison.

In primary influenza viral pneumonia, virus infection reaches the lung either by contiguous spread from the upper respiratory tract, or by inhalation of small-particle aerosols. Infection initially occurs in ciliated respiratory mucosal epithelial cells of the trachea, bronchi, and lower respiratory tract, and leads to widespread destruction of these cells. The trachea and bronchi contain bloody fluid, and the mucosa is hyperemic. Tracheitis, bronchitis, and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular, hyaline membranes line many of the alveolar ducts and alveoli.

The pathologic changes in the lower respiratory tract in children with viral pneumonia due to RSV and parainfluenza virus are nonspecific and include epithelial necrosis with bronchiolar mucus plugging and widespread inflammation and necrosis of lung parenchyma, and severe lesions of the bronchial and bronchiolar mucosa as well. In fatal cases of RSV pneumonia in children, hemorrhagic pneumonia with peribronchial mononuclear infiltration and cytoplasmic inclusion bodies in epithelial cells are seen.

Bacterial superinfection is a well-recognized complication of viral pneumonia and accounts for a large proportion of the morbidity and mortality of viral lower respiratory tract disease, especially in adults. Consequently, the spectrum of disease and pathophysiology of bacterial superinfection has been studied intensively, and a number of factors have been identified in viral respiratory disease that could play a role in increasing the risk of bacterial infection.[80] The disruption of the normal epithelial cell barrier to infection, and loss of mucociliary clearance, undoubtedly contribute to the enhancement of bacterial pathogenesis. The physiologic consequences of these alterations have been demonstrated as markedly decreased mucociliary clearance of labeled particles in human subjects with acute, naturally acquired influenza.[81] Animal models have also suggested that virally induced inflammatory responses, particularly the type I interferon response, also contribute to the downregulation of host antibacterial defense mechanisms.[82,83]

Viral Etiologies and Differential Diagnosis

The impact of viral pneumonia and the spectrum of associated viral agents is highly dependent on the age group and immune status of the host. Viruses are clearly important and frequent causes of pneumonia in young children. The role of viruses becomes less apparent in older children; in healthy adults, pure viral pneumonia is rare and is predominantly due to influenza. Elderly adults may experience more significant lower respiratory tract signs and symptoms following infection with agents that normally cause upper respiratory tract illness in younger adults, but generally have similar rates of viral pneumonia as do healthy young adults. Finally, viral pneumonia is an important cause of morbidity and mortality in individuals with compromised immune systems, with a broader spectrum of viral agents than seen in immunologically intact individuals. The following sections outline the features of the most common viruses associated with lower respiratory tract infection and viral pneumonia.

Influenza

Influenza is a prevalent infection that has wide-reaching implications for large populations of patients.

Clinical Features The onset of influenza is typically abrupt, and the illness is characterized by the predominance of systemic symptoms, including fever, prostration, myalgias, and malaise. Respiratory symptoms may be relatively minimal, particularly early in the course, and include nasal complaints, sore throat, hoarseness, and nonproductive cough. Because of the involvement of tracheal epithelium in infection, complaints of burning throat and substernal pain may be seen. Among healthy adults, the best clinical predictors of influenza virus positivity are the presence of cough and fever in patients presenting during epidemics.[84]

Other than fever, there are usually few findings on physical exam. Affected individuals may exhibit rhinitis, pharyngitis, conjunctival injection, and tracheal tenderness. The chest is usually clear in uncomplicated cases. Most acute symptoms resolve in 3 to 5 days, but complete recovery may take weeks. The clinical features of influenza A and B virus infection are similar. Symptoms of influenza in children are similar to those in adults, although children may have higher fever with febrile seizures. As described earlier, influenza may be associated with otitis media or croup in children.

Primary influenza viral pneumonia is characterized by rapid progression of dyspnea, cough and cyanosis, and development of respiratory distress syndrome acute (ARDS). Chest roentgenographs reveal bilateral interstitial infiltrates, sputum production is scanty, and Gram stain reveals few organisms. Secondary bacterial pneumonia may present 1 to 2 weeks after apparent recovery from an acute influenza episode with recurrence of fever, and signs and symptoms of typical lobar pneumonia. Many patients present with mixed viral and bacterial pneumonia. Bacterial superinfections of influenza have been postulated as a major cause of death during the pandemic of 1918.[85] The most common bacteria implicated are *Streptococcus pneumoniae*, with a significantly increased frequency of *Staphylococcus aureus*[86,87] including methicillin-resistant staph (MRSA).[88]

Influenza A and B viruses are both significant causes of pneumonia in children, especially during periods of epidemic prevalence. In infants and children, the most frequent manifestation of influenza pneumonia is an interstitial pneumonitis similar in appearance and course to those of the other predominant viral agents of pneumonia in this age group, except that a secondary bacterial pneumonia may occur more frequently than with RSV or parainfluenza viruses.

Epidemiology Influenza is typically associated with seasonal epidemics of greater or lesser severity, which occur during the winter months in temperate climates in both the northern and southern hemispheres. Outbreaks in the northern hemisphere are usually noted between the months of November and March or April, and typically last from 4 to 6 weeks in any given community. The reasons for the seasonal behavior of influenza are not known but have been the subject of much interest. Some suggested mechanisms have included the seasonal effects of heat and humidity on the viability of virus in the environment, behavioral patterns that facilitate transmission, such as attendance at schools, or sunlight effects on baseline immune function.

Seasonal influenza epidemics are regularly associated with excess morbidity and mortality,[89] and both influenza A and B can be associated with severe illness. During inter-pandemic years, influenza is characterized by a "U-shaped" epidemic curve, in which attack rates and medically attended illness rates are generally highest in infants and young children, whereas mortality is generally highest in the elderly. Young children are generally more susceptible to influenza infection than are adults, and they shed higher levels of virus for longer periods. Healthy children younger than 1 year of age are hospitalized for influenza at rates comparable to those of older children and adults with chronic high-risk conditions[90,91] and are special targets of prevention measures.

Excess morbidity and mortality are particularly high in those with underlying medical conditions, including chronic cardiovascular or pulmonary disease, chronic metabolic disease including diabetes mellitus, renal dysfunction, hemoglobinopathies, or immunodeficiency, including HIV. Recently, it has been recognized that individuals with neuromuscular conditions affecting the ability to clear respiratory secretions,[92] and persons with morbid obesity,[93] also are at high risk for influenza hospitalization. Women in all stages of pregnancy, and in the immediate postpartum period, also have increased rates of hospitalization, ICU admission, and deaths during influenza epidemics.[94,95]

Antigenic variation is the hallmark of the epidemiology of influenza, and occurs in two forms referred to as antigenic "drift" and antigenic "shift." Drift refers to the gradual accumulation of mutations, primarily in the hemagglutinin (HA) and neuraminidase (NA) proteins of the virus, that allow the virus to escape from antibody generated against previous strains. New, drifted strains generally appear every several years and tend to replace previous strains. Antigenic drift occurs in both influenza A and influenza B viruses. In addition, recent influenza B viruses have evolved into two antigenically distinct lineages termed the "Yamagata" and "Victoria" lineages,[96,97] which currently cocirculate.

Influenza A viruses exist as multiple antigenically distinct HA or NA subtypes. There are currently 17 recognized HA subtypes (H1–H17) and 9 recognized NA subtypes (N1–N9), although current seasonal viruses are restricted to the H1N1 and H3N2 subtypes. When one influenza A subtype is replaced by another, a phenomenon recognized as antigenic shift, the new virus encounters a population with little or no prior immunity. Worldwide epidemics of severe disease, referred to as pandemics, are usually the result.

Pandemics associated with antigenic shift have been noted multiple times in the twentieth and twenty-first centuries. In 1918 H1N1 viruses emerged and replaced previous H3N2 viruses, in 1957 H2N2 viruses replaced H1N1 viruses, and in 1968 H3N2 viruses replaced the H2N2 viruses. In 1977, an H1N1 virus antigenically similar to H1N1 viruses from 1950 emerged to cause disease primarily in those born after 1950 but did not replace previous H3N2 viruses. Finally, in 2009 a new H1N1 virus (the so-called pH1N1 virus) emerged that was antigenically similar to H1N1 viruses prior to 1947 and caused disease predominantly in young adults and children. Since then, both H3N2 and pH1N1 viruses have circulated in humans. Influenza A viruses are zoonotic in multiple animal species including migratory waterfowl and swine, and epidemiologic data strongly support the notion that new pandemic influenza A viruses arise from this reservoir (see below).

Pathogenesis The mechanisms responsible for transmission of influenza viruses from person to person have never been completely defined, and it is likely that both large particles (i.e., droplet) and small particles (aerosol) released from the airway during coughing and sneezing play a role. Once virus is deposited on the respiratory tract epithelium, it can attach to and penetrate columnar epithelial cells if not prevented from doing so by specific secretory antibody (IgA), by nonspecific mucoproteins to which virus may attach, or by the mechanical action of the mucociliary apparatus. The duration of the incubation period to the onset of illness and virus shedding varies from 18 to 72 h depending in part on the inoculum dose. Viral shedding in the respiratory tract is first detected just before the onset of illness (within 24 h), rapidly rises to a peak and remains elevated for 24 to 48 h, and then rapidly decreases to low titers. Usually, influenza virus is no longer detectable after 5 to 10 days of virus shedding. Both the duration and the level of virus shedding are typically longer in young children than in adults. In general, the course of the clinical illness correlates temporally with the pattern of virus shedding, and severity is correlated with the quantities of virus shed.

Bronchoscopy of individuals with typical, uncomplicated acute influenza has revealed diffuse inflammation of the larynx, trachea, and bronchi, with mucosal injection and edema. Histologic findings on autopsy of more severe cases show extensive necrotizing tracheobronchitis, with ulceration and sloughing of the bronchial mucosa, extensive hemorrhage, hyaline membrane formation, and a paucity of polymorphonuclear cell infiltration. Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter,[98] as well as increased responses to bronchoprovocation. In addition, abnormalities of carbon monoxide diffusing capacity and increases in the alveolar–arterial oxygen gradient have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery.

Diagnostic Tests Rapid viral diagnosis based on immunologic detection of viral antigen in respiratory secretions is widely used for influenza diagnosis. All these tests are designed to detect both influenza A and B, but only some of the tests differentiate between the two. Some of the tests that are minimally complex may be eligible for waivers that allow them to be used in the office setting. In general, sensitivities in adults and elderly patients tend to be lower than reported in young children, who tend to shed much larger quantities of virus in nasal secretions and therefore have much higher concentrations of antigen in their samples. Although all types of respiratory samples can be used in such tests, the sensitivity appears to be better with nasopharyngeal swabs and aspirates than with throat swabs or gargles.

Molecular diagnostic tests are also widely available for influenza diagnosis and are frequently coupled with detection of other respiratory viruses, especially RSV. Nasopharyngeal samples remain the most sensitive of samples, but it has been noted that in some patients with pneumonia, sputum samples have been positive when nasal samples were negative. As is the case for all diagnostic testing, specific influenza testing should be focused on those cases where a specific diagnosis will have implications for therapy or infection prevention.[99]

Treatment and Prevention Below are considered treatment options for influenza treatment, as well as recommendations for prevention.

Antiviral Therapy Available antiviral agents for influenza are summarized in Table 126-3. The currently most widely used antiviral agents for influenza are the neuraminidase inhibitors, selective inhibitors of the neuraminidase enzymes of both influenza A and B viruses. In cell culture, inhibition of neuraminidase function is predominantly manifested as inhibition of cell-to-cell spread of virus. Currently available neuraminidase inhibitors include orally administered oseltamivir, intravenously administered peramivir, and inhaled zanamivir. Results of clinical trials of these products have been very similar, with excellent safety profiles.

As a general principle, it is clear that early initiation of therapy is critical to the effectiveness of antiviral therapy of acute influenza. This general observation is consistent with the typical pattern of

TABLE 126-3 Antivirals Active Against Influenza

Drug	Dosage in Adults	Dosage in Children	Comments
Oseltamivir	75 mg PO bid for 5 days	≤15 kg: 30 mg twice daily >15–23 kg: 45 mg twice daily >23 kg: 60 mg twice daily >40 kg: 75 mg twice daily	• Controlled trials available in adults, elderly, and children • Approximately 1- to 2-day earlier resolution of symptoms, reduced otitis in children • Other effects demonstrated include earlier return to work, decreased diagnosis of bronchitis • Metaanalysis shows reduced hospitalization rates • Well tolerated, main adverse event is nausea
Zanamivir	10 mg via inhalation bid for 5 days	≥7 years: 10 mg via inhalation twice daily <7 years: Not recommended	• Similar safety and efficacy profile as oseltamivir, without nausea • Reports of exacerbations of reactive airways disease
Peramivir	600 mg IV once daily or, if severe, for up to 5–10 days	Infants ≥6 months and children: 12 mg/kg as a single IV dose; maximum dose: 600 mg/dose; can be used for up to 5–10 days	• For those who can't tolerate oral therapy
Baloxavir marboxil	<80 kg: 40 mg as a single dose within 48 h of onset of influenza symptoms (if >80 kg, dose is 80 mg)	Oral: 2 mg/kg once as a single dose; maximum dose: 40 mg/dose	• Emergence of resistance after a single dose raises concerns about the long-term utility of this drug as monotherapy
Amantadine	<65 years: 100 mg twice daily for 5 days	1–9 years: 5 mg/kg/d, not to exceed 150 mg/d in two divided doses 10–12 years: 100 mg twice daily	• High levels of resistance in current influenza A viruses; no longer used for treatment of influenza
Rimantadine	100 mg twice daily for 5 days	≤12 years: Not recommended	• High levels of resistance in current influenza A viruses; no longer used for treatment of influenza • Not approved for use in children

viral shedding in an immunologically primed individual in which the peak of virus shedding is in the first few days of illness and is rapidly controlled by the immune system. Therapy initiated beyond 48 h of symptoms does not appear to be useful in immunocompetent adults and children, and the greatest benefit is seen when therapy is begun within 12 or 24 h after the onset of symptoms. Relatively little controlled data are available related to the use of antivirals in immunocompromised individuals with influenza or in primary influenza infections, and it is unclear whether these same constraints would apply in these situations.

Metanalysis of results of these trials has also suggested that early treatment may reduce the frequency of influenza-related complications, with reductions in the use of antibacterials and in hospitalization.[100] However, pooled analyses of these studies of early therapy with zanamivir[101] and oseltamivir[100,102] demonstrated a significant reduction in the rate of influenza complication in treated individuals. The subsequent experience in the epidemic of pH1N1 virus has also suggested a beneficial effect of early therapy on complications. These include observations in hospitalized patients[103,104] and surveillance data suggesting that therapy as late as 5 days improved survival of hospitalized patients.[105] Surveillance data have also suggested that treated children had lower rates of complications.[106]

Resistant viruses have been detected in treated patients, most commonly in children. Beginning in 2006, spontaneously resistant H1N1 viruses carrying a specific neuraminidase mutation H274Y began to spread, and by 2008 all H1N1 viruses isolated in the United States were resistant. Of note, emergence and spread of resistant viruses was spontaneous and did not occur in the context of widespread uses of these drugs.[107] Fortunately, the emerging pandemic H1N1 virus, which subsequently replaced previous seasonal H1N1, has remained susceptible to neuraminidase inhibitors.[108]

Baloxavir marboxil is an orally administered inhibitor of the endonuclease subunit of the influenza polymerase trimer and has in vitro activity against both influenza A and B viruses. In a recent, large, randomized clinical trial, a single dose of baloxavir was as effective as a 5-day course of oseltamivir in alleviation of symptoms in H3N2-infected subjects and led to a more rapid decline in viral shedding.[109] However, viruses with reduced susceptibility to baloxavir due to specific mutations in the PA protein (I38T/M) were found frequently, and this was associated with a less rapid resolution of symptoms. Of note, such variants seemed to be most common in individuals with low baseline neutralizing antibody against the virus.[110] Since licensure, resistant viruses have been frequently detected in treated children.[111] Resistant viruses may be less fit in vitro, but human-to-human transmission of resistant variants has been identified in household contacts.[112] Baloxavir is currently approved in the United States for single-dose treatment of acute influenza of 48 h duration or less in individuals 12 years and older.

A third class of antiviral agent is the adamantanes (amantadine and rimantadine), whose mechanism of action is the result of inhibition of the viral M2 protein, an ion channel involved in viral uncoating. M2 inhibitors are active only against influenza A viruses. Although M2 inhibitors were highly effective drugs for prophylaxis and therapy of influenza A, resistant viruses were also generated quite readily in treated individuals.[113] Despite relatively infrequent use of these agents, resistant viruses emerged and spread worldwide in the 1990s, and almost all influenza A viruses are now completely resistant to M2 inhibitors[114] and they are no longer used for treatment of influenza. Along with experience with other antiviral agents, the rapid development of antiviral resistance remains an important consideration in the development of specific therapies.

Although the benefits of antiviral therapy were initially demonstrated as a shortening of illness duration in healthy adults with uncomplicated influenza, this is generally not considered the priority target group for antiviral therapy. Current recommendations

TABLE 126-4 Current Influenza Vaccines

	SD IIV-4	HD IIV-4	ccIIV4	rIV4	aIIV3	LAIV4
Formulation	Inactivated split virus or subunit	Inactivated split virus	Inactivated subunit	Recombinant HA protein	Inactivated subunit plus MF59 adjuvant	Live attenuated influenza viruses
Dose	15 μg/HA	60 μg/HA	15 μg/HA	45 μg/HA	15 μg/HA	10^7 FFU/virus
Number of HAs	4 (H1, H3, BV, BY)	4 (H1, H3, BV, BY)	4 (H1, H3, BV, BY)	4 (H1, H3, BV, BY)	3 (H1, H3, B*)	
Substrate	Eggs	Eggs	MDCK cells	Insect cells	Eggs	Eggs
Age indication	≥6 months	≥65 years	≥4 years	≥18 years	≥65 years	2–49 years

HA, hemagglutinin; BV, influenza B Victoria lineage; BY, influenza B Yamagata lineage; B, only one lineage is included.*

include the use of antivirals in individuals at risk for more severe influenza, or in individuals with severe disease or requiring hospitalization.[115] Treatment should be started as early as possible, but even delayed therapy can be of benefit in hospitalized patients. Given the totality of available data, oseltamivir is generally recommended as the first choice for seriously ill patients. For outpatients with suspected or confirmed uncomplicated influenza, oral oseltamivir, inhaled zanamivir, or oral baloxavir may all be used for treatment. In addition to those options, for hospitalized patients, intravenous peramivir would also be used.

Vaccines for Influenza Multiple formulations of influenza vaccines are currently available for prevention of influenza (Table 126-4). Influenza vaccines are designed to induce primarily serum antibody to the hemagglutinin and neuraminidase, although other mechanisms of protection also may be induced. Multiple formats of vaccines are available, including inactivated, chemically disrupted, and purified HA and NA antigens generated from viruses grown in embryonated hen's eggs or from viruses grown in cell culture, as well as purified HA recombinant protein expressed in insect cells using baculovirus technology. Virion-based vaccines are typically formulated to contain 15 μg of each HA in the final product, while the recombinant vaccine contains 45 μg, and a high-dose vaccine containing 60 μg of each HA is licensed for use in individuals 65 and older. The saponin adjuvant MF59 is included in one of the vaccines to improve the antibody response in older recipients. Current vaccines contain one example of influenza A (H1N1) and A (H3N2), based on the most current epidemiologic predictions of the likely circulating strains in the coming season, and may contain one example of influenza B or examples of both influenza B lineages. Current recommendations do not include a preference for any specific vaccine, although this may change as more data become available.

A live attenuated influenza vaccine is also available, designed to induce mucosal antibody in the respiratory tract, although specific correlates of protection have not been developed. This vaccine is generated by genetic reassortment between circulating wild-type strains and attenuated master donor viruses for both influenza A and B and is currently formulated as a quadrivalent preparation. The live vaccine is currently licensed for use in adults and children from 2 to 49 years of age.

Current recommendations for prevention of influenza in the United States[116] and several other countries call for a strategy of universal vaccination, in which vaccine is offered annually to the entire population. Efforts at vaccination should be especially targeted at persons who, for reasons of age or medical conditions, are at increased risk for developing complications, hospitalization, or death due to influenza, and contacts who may transmit infection to these high-risk individuals. Persons who may transmit to high-risk persons include family members, out-of-family caregivers, and importantly, health care providers.

Respiratory Syncytial Virus

Respiratory syncytial virus frequently causes detectably altered airway reactivity in adults, and on occasion, lower respiratory tract involvement becomes clinically manifest as pneumonia in otherwise healthy adults. RSV is being increasingly recognized as a cause of significant lower respiratory tract disease in the elderly.[117] It has been estimated that 2% to 4% of pneumonia deaths among the elderly in the United States may be due to RSV.[118]

In most series, RSV has been associated with the largest proportion of viral pneumonia in young children, particularly if accompanied by bronchiolitis. It should be noted in this regard that bronchiolitis and pneumonia represent a spectrum of lower respiratory tract involvement with RSV, frequently coexist, and are not clearly distinguishable. The most typical finding is diffuse interstitial pneumonitis (Fig. 126-1). Lobar or segmental consolidation are evident by CXR in about one-fourth of children with RSV lower respiratory tract disease.

RSV has been well recognized as a cause of pneumonia in recipients of bone marrow[119] and solid organ transplantation.[120] Nosocomial transmission of RSV in this setting has been well documented and may be the source of many infections in this susceptible population. The illness typically begins with nondescript upper respiratory symptoms that progress over several days to severe, life-threatening lower respiratory tract involvement. Mortality rates of 50% or higher are typical, particularly if disease occurs in the pre-engraftment period.

Parainfluenza Virus

The parainfluenza viruses are most typically associated with viral pneumonia in children, particularly serotype 3 (PIV3). However, occasionally these viruses may be associated with pneumonia in adults. Frequent contact with small children is probably a risk factor.

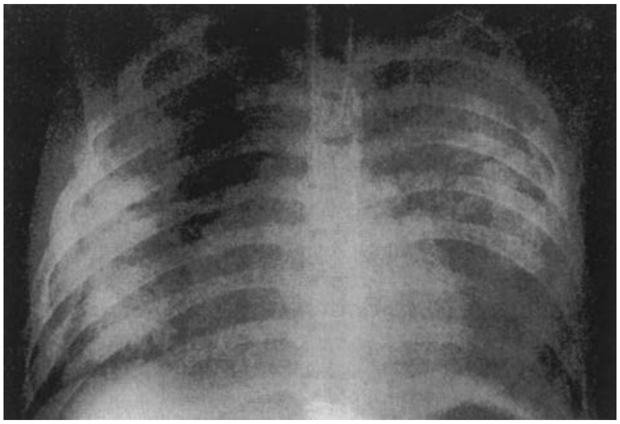

Figure 126-1 Premature infant at 3 months of age with respiratory syncytial virus pneumonia. *(Reproduced with permission from Duchin JS, Koster FT, Peters CJ, et al. Hantavirus pulmonary syndrome: a clinical description of 17 patients with a newly recognized disease. The Hantavirus Study Group. N Engl J Med. 1994;330(14):949–955.)*

Parainfluenza viruses have occasionally been reported as causes of pneumonia in adults and in the elderly.[121] Parainfluenza viruses have also been reported as an infrequent lower respiratory tract pathogen in both solid organ and bone marrow transplantation. PIV3 has been the most common serotype isolated, but all four serotypes have been implicated.

There are no licensed vaccines or antiviral agents for parainfluenza virus. DAS 181 is an inhaled sialidase linked to a respiratory epithelium–binding domain. The product can remove sialic acid from the epithelial cells of the respiratory tract, thereby inhibiting viruses that rely on such receptors. Clinical trials have not shown benefit in influenza, but there are reports of compassionate use of the drug to treat parainfluenza infections of the lower respiratory tract in lung transplant recipients.[122]

Adenovirus

Adenovirus was first recognized as a cause of viral pneumonia in military recruits and has since been recognized as a rare cause of pneumonia in civilian adults and children. Outbreaks in institutionalized populations occur. The clinical characteristics of adenovirus pneumonia are similar to those of other pneumonias, so that it is difficult to make an accurate etiologic diagnosis on the basis of clinical features. In fatal cases there has been extensive pulmonary damage, with death occurring 2 to 3 weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases, and a septic shock picture has been described. Bacterial superinfection, particularly with *N. meningitidis*, may occur. Since 1996, a specific variant of adenovirus type 7 (Ad7d2) has been responsible for several civilian outbreaks and a large military outbreak. The appearance of new Ad 7 genotypes may herald a shift in the predominant strains with greater disease impact.[123] Recent reports have emphasized the emergence of a relatively rare adenovirus serotype 14 responsible for severe community acquired pneumonia in adults and children.[124]

Adenoviruses are frequently isolated from children with respiratory disease and are implicated in about 10% of childhood pneumonias. However, the true impact of adenoviruses as causes of pneumonia in this age group is difficult to assess because of the long and intermittent asymptomatic respiratory shedding of these viruses in children. Hilar adenopathy on CXR is somewhat more common with this form of pneumonia than other types.

Adenoviruses are significant causes of morbidity and mortality in immunocompromised patients, particularly after transplantation. In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with isolation of virus from multiple body sites including lung, liver, gastrointestinal tract, and urine.[125] In addition, the spectrum of serotypes includes both those found in immunocompetent individuals as well a markedly increased frequency of isolation of higher-numbered serotypes found rarely in immunologically normal subjects.

Antiviral treatment of proven value for adenovirus infection is not available. Both the broad-spectrum antiviral agents ganciclovir and cidofovir are active in vitro. Cidofovir has also been used for preemptive therapy in high-risk immunocompromised patients.[126] Brincidofovir is an oral formulation of cidofovir that also is being evaluated as a potential therapeutic.[127]

Measles

Pneumonia is the most frequent serious complication of measles. The prodrome of typical measles lasts 2 to 8 d and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucous membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically disappears after 5 to 6 d in the order in which it appeared. Defervescence and symptom improvement occur several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (less than 2000 cells/mm^3) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

Measles can be complicated by clinically severe pneumonitis in a small percentage of healthy adults, and bacterial superinfection is common.[128] In patients with altered cell-mediated immune function, and rarely in apparently normal persons, infection by wild measles virus can cause a lethal giant cell pneumonia with or, in about 30% of patients, without rash.[129] Measles has largely been controlled by vaccination, but outbreaks continue to occur.

Measles giant cell pneumonia is a severe, usually fatal form of pneumonia associated with measles infection in immunosuppressed individuals. Most cases have occurred in those with hematologic or other malignancies, or individuals with AIDS. Recent outbreaks of measles worldwide, coupled with the increasing incidence of HIV infection, have increased the frequency and impact of measles giant cell pneumonia. Giant cell pneumonia also occurs in significantly malnourished individuals. Multinuclear giant cells with intranuclear inclusions are seen and may be demonstrable in fluid obtained by bronchoalveolar lavage. An important feature of measles pneumonia in immunocompromised hosts is that many patients present without rash or other typical manifestations of measles, and a high index of suspicion must be maintained. It has been speculated that such hosts may not mount the cellular immune responses involved in the pathogenesis of rash in immunologically intact individuals. In hospitalized patients, mortality rates are approximately 70% in oncology patients and 40% in HIV-infected patients.[130]

Varicella Zoster Virus

Viral pneumonia is the major complication of varicella zoster virus (VZV) in normal adults, in whom it occurs with an estimated 25-fold higher frequency than in children.[131] Smoking is a significant risk factor. Pneumonia associated with varicella is usually apparent 1 to 6 d after the onset of rash. Symptoms include cough, dyspnea, pleuritic chest pain, and hemoptysis. Physical findings other than fever and tachypnea are often modest. The intensity of the rash does not necessarily correlate with the severity of pneumonia. The characteristic radiographic pattern is that of diffuse nodular (1–10 mm) infiltrates, which may resolve with miliary calcific densities. Hilar adenopathy, pleural effusions, and peribronchial infiltrates are frequently present. Pulmonary infarction may complicate the clinical picture. Pulmonary function studies have found normal spirometric values but decreased carbon monoxide diffusing capacity, which may persist for months. One prospective radiologic study of military recruits with varicella found abnormalities in approximately one in six patients, but only one-fourth of those with radiographic changes had cough, and none experienced severe disease.[132]

VZV is an important problem in individuals with hematologic malignancies and others with iatrogenic immunosuppression, with the greatest risk seen in organ transplantation. Prolonged fever and/or recurrent crops of lesions are predictors of visceral dissemination, and pneumonia is generally seen in this setting. Pulmonary manifestations may include pleuritic chest pain due to vesicular lesions of the pleura, and, as is also true in normal hosts, the CXR may demonstrate nodular lesions.

Cytomegalovirus

CMV is frequently detected in respiratory samples from immunosuppressed individuals, particularly transplant recipients, or individuals infected with the human immunodeficiency virus

(HIV) with severe pneumonia. The highest risk in the transplant population is 1 to 3 months post-transplantation, with the peak incidence at 8 weeks post-transplant. Diffuse interstitial pneumonitis is the most frequent presentation, but multiple other CXR presentations have been reported, including nodular infiltrates resembling *Nocardia*. Multiple associated findings are present in severe infection and reflect the disseminated nature of the infection; the presence of neutropenia, abnormalities of liver function tests, and mucosal ulcerations may be clinical clues to the diagnosis.

Characteristically, patients with CMV pneumonia have sustained fever, nonproductive cough, and dyspnea. Rales and tachypnea are often present, and marked hypoxemia is an indicator of life-threatening infection. Pneumonitis may be accompanied by mild neutropenia, thrombocytopenia, and elevated liver enzymes, which may be helpful in differential diagnosis. Chest radiographic changes are usually bilateral, with diffuse or focal haziness involving the mid and lower lung fields. Both miliary and interstitial radiographic patterns have been described. Often the perihilar distribution of the infiltrate is suggestive of pulmonary edema. Common CT scan findings include small nodules, consolidation, and ground-glass attenuation.

Cytomegalovirus pneumonia is a problem predominantly in individuals with compromised immune systems, particularly after transplantation, and represents a systemic infection that involves the lung secondarily. There are several features of this disease in the transplant setting that suggest that both host and viral factors interact in pathogenesis.[133] CMV pathogenicity is enhanced in transplant recipients and frequently occurs at the site of the transplanted organ. The risk of CMV pneumonitis is highest in individuals at the highest risk for graft-versus-host disease. In transplant patients, the detection of CMV by itself does not necessarily indicate end-organ involvement. For transplant patients, it has been suggested that higher levels of CMV in pulmonary specimens may be more indicative of CMV pneumonia.[134] Assessing the role of CMV in an immunosuppressed patient can be challenging, since in HIV patients CMV is frequently detected along with other pathogens, such as *Pneumocystis*, and its role in the pneumonia can be unclear.[135]

The pathogenesis of CMV pneumonia is partly related to viral replication but is also thought to have an immunopathologic basis.[136] The development of CMV pneumonitis reflects a complex interaction between viral infection and graft-versus-host disease, particularly in marrow transplant recipients. Two patterns of histopathology have been described in the lung tissue of bone marrow transplant patients with serious pneumonia. One is a miliary pattern, with multiple focal lesions showing extensive cytomegaly with localized necrobiosis, alveolar hemorrhage, fibrin deposition, and neutrophilic response. The other is of interstitial character, with alveolar-cell hyperplasia, interstitial edema, lymphoid infiltration, and diffusely distributed cytomegalic cells.

Guidelines for reducing the risk of CMV disease in stem cell and solid organ transplant recipients have been published.[137] Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors should receive only leukocyte-reduced or CMV-seronegative RBCs and/or leukocyte-reduced platelets. In mismatched solid organ transplant recipients (donor+/recipient−), posttransplant prophylaxis with valganciclovir significantly reduces the risk of CMV disease, although late-onset disease still occurs.[137] Another strategy is preemptive therapy with valganciclovir or another anti-CMV agent when weekly screening detects early infection.

Herpes Simplex Virus

HSV infection of the lower airway may occur either as the result of direct extension of infection from the tracheobronchial tree to the lung or as the result of hematogenous dissemination of virus from mucocutaneous lesions of the upper airway or genitourinary tract. Dyspnea, cough, and hypoxemia are usually seen, but the clinical features of the pneumonia generally do not permit an etiologic diagnosis to be made antemortem. Focal or multifocal infiltrates are thought to indicate direct extension, whereas diffuse bilateral infiltrates may occur due to presumed hematogenous dissemination of virus.[138] CT scan findings include multifocal segmental and subsegmental ground-glass opacities[139] but are not distinctive. In one study, more than one-half of the patients had concomitant pulmonary infection with other microorganisms, including bacteria, *Candida* and *Aspergillus* species, and cytomegalovirus.

Isolation of HSV from lower respiratory tract secretions is common in mechanically ventilated patients and may be associated with a poor outcome.[140] However, clinical outcomes of HSV-positive patients are not significantly different from those of HSV negative patients,[141] and it can be difficult to determine whether HSV is playing a specific role in the lower respiratory tract disease.

Acyclovir is active in vitro against herpes simplex virus types 1 and 2; it is approximately tenfold less active against VZV and does not have clinically useful activity against cytomegalovirus or Epstein-Barr virus. Although controlled clinical trials of this drug in herpes simplex pneumonia have not been conducted, the drug has proven clinical efficacy in other herpesvirus infections and would be indicated in any serious HSV lower respiratory tract infection. Acyclovir is also effective in the therapy of varicella, and intravenous acyclovir has been effective when initiated early in the course of varicella pneumonia. Viruses resistant to acyclovir have been isolated from treated patients, albeit rarely, and may be susceptible to foscarnet.

Emerging Viruses

The potential for novel viruses that normally infect animal species to be transmitted to humans and spread rapidly represents a potential public health threat of increasing concern. There have been multiple examples of this phenomenon in recent years, and developing strategies to rapidly and effectively respond to such emerging threats is a critical public health goal. Examples of the emergence of highly lethal viruses that originated from animal species are briefly described below.

Novel Coronaviruses In recent years, three previously undescribed coronaviruses have emerged to cause severe lower respiratory tract illness in humans. The first epidemic to be recognized was referred to as severe acute respiratory distress syndrome, or SARS. Epidemics of SARS were initially recognized in southern China in 2003 and subsequently spread throughout the world. The etiologic agent was identified as a novel coronavirus, designated the human SARS coronavirus[142] and currently referred to as SARS-CoV. After an intense epidemic associated with 8096 cases and 774 deaths, the disease disappeared, largely due to aggressive infection control practices. Virus shedding was at its peak at the time that illness was most severe,[143] and the preponderance of transmission occurred in the hospital setting. Ultimately, this allowed the pandemic to be controlled largely by isolation and other infection prevention procedures. Then in 2012, cases of a similar severe respiratory illness were recognized in a variety of Middle Eastern countries. This illness, now referred to as the Middle Eastern respiratory syndrome, has been named MERS-CoV. In contrast to SARS, little if any sustained person-to-person transmission has been observed to date with MERS-CoV, although obviously there is concern that the virus could gain this ability at some later time.

Because of the far greater number of cases of SARS, much more is known about the presentation and clinical features of pneumonia due to this virus. The most common symptoms on presentation were fever, chills and/or rigors, and myalgias. Cough and dyspnea were the predominant respiratory symptoms but were not always present initially. Upper respiratory symptoms, such as rhinorrhea or sore throat, were infrequent. In addition, about one-third of patients had diarrhea at some point in the clinical course. Respiratory disease was progressive and became more severe over 4 to 7 d, leading to significant hypoxemia. About 20% of patients required respiratory support. The overall case fatality rate was about 10% but was much higher in older adults. In contrast, children appeared to have milder disease.[144] To date, MERS has had a similar presentation to SARS, although gastrointestinal symptoms may be more prominent.[145] Common findings on CT included ground-glass opacification and interlobular septal and intralobular interstitial thickening. Pulmonary fibrosis developed in some patients after recovery from the acute illness.[146]

Around November of 2019, a new antigenically distinct coronavirus emerged and spread rapidly around the world. The virus was subsequently named the severe acute respiratory syndrome coronavirus type 2, or SARS-CoV-2, and the resulting disease syndrome referred to as coronavirus infectious disease 2019, or COVID-19. Unlike the previous SARS and MERS coronaviruses, efficient person-to-person transmission of SARS-CoV-2 occurs prior to the development of severe disease, substantially impacting control of the spread of the virus using traditional quarantine approaches that had ultimately proved successful for control of SARS. Within just a few months, the virus had spread worldwide, with devastating public health impact.

All three of these viruses were genetically similar to coronaviruses found in bats, which may represent the population from which the viruses were ultimately derived. There is substantial interest in the ability of bats to harbor diverse varieties of viruses, including hantaviruses, Nipah viruses, influenza viruses, and others. In part this may be related to the very large and diverse species of bats, but it may also be related to unique properties of the bat immune system that allow viral infection without the development of illness.[147] However, there are significant genetic differences between closely related bat viruses and subsequent human isolates, suggesting a role for intermediate mammalian hosts. In the case of SARS, this was suggested to possibly be the palm civet, while for MERS camels clearly play an important role. The specific intermediate host for SARS-CoV-2 remains to be determined.

Clinical Features of COVID-19 A wide variety of presenting clinical symptoms have been described for COVID-19. Frequently, the illness begins with upper respiratory symptoms such as runny nose and sore throat and progresses over several days to fever, malaise, cough, and gradually increasing dyspnea and hypoxia. In initial reports of disease in Wuhan, the most common symptoms were fever, fatigue, and dry cough. Other associated signs and symptoms include loss of sense of smell or taste, diarrhea or other gastrointestinal symptoms, and development of discoloration of the fingers and toes (chilblains). Typical CT findings include bilateral patchy shadows or ground-glass opacity in the lungs typical of viral pneumonia.[148,149] Other common findings include consolidation, pleural thickening, interlobular septal thickening, and air bronchograms.[150] Respiratory failure is usually the immediate cause of death in fatal cases. Although the denominator of total cases can be difficult to ascertain, it is estimated that approximately 10% of cases require hospitalization, with a case fatality rate on the order of 1%.

A variety of serious and severe complications of COVID-19 have been described. These include pulmonary fibrosis; blood coagulation complications such as deep-vein thrombosis, pulmonary embolism, and cerebrovascular accidents; neurologic complications including transverse myelitis and encephalitis; and cardiac complications including development of myocarditis and heart failure. These effects may persist well beyond the resolution of the acute illness. Recovery from COVID-19 may also be complicated by the persistence of a variety of poorly understood effects, such as long-term difficulties with mentation (referred to as "brain fog"), chronic fatigue, and elements of posttraumatic stress disorder. The specific pathogenesis and appropriate treatment of such "long-haul" effects are unknown at this time.

Several features have been identified as risk factors for severe disease and death. These include age, with older subjects at much higher risk, and a number of medical conditions, such as obesity, diabetes, hypertension, cardiovascular disease, chronic lung disease, chronic kidney disease, and immunosuppressive illnesses. However, a substantial number of hospitalizations have occurred in young, otherwise healthy individuals as well. Rates of symptomatic disease appear to be substantially lower in young children, for unclear reasons. However, a multisystem inflammatory syndrome in children (MIS-C), resembling Kawasaki disease, has been associated with COVID-19. There is no demographic group that is not affected by the COVID-19 pandemic.

Epidemiology of COVID-19 Infection is associated with rapid viral replication, and titers of nasopharyngeal virus are typically highest early in the course of illness, facilitating the likelihood of transmission before severe illness is recognized. Transmission of virus from person to person can occur by direct contact, droplet spread, and aerosol, although the relative contribution of each mode of transmission is unclear. As a result, nonpharmaceutical control measures have included personal hygiene, social distancing, use of masks and personal protective equipment, avoiding indoor gatherings, and improving air flow in indoor spaces. Observational studies have suggested that each of these measures has reduced the rate of transmission.

Factors impacting transmission in the community are poorly understood. As the pandemic virus was introduced into various countries, the numbers of detected cases expanded rapidly, with estimates of initial reproductive number (R0) of 2 to 3 and serial interval of 4 to 7 days. Increases in hospitalizations and mortality then occurred approximately 2 to 3 weeks later. In most outbreaks, the rates of new cases slowly declined as various nonpharmaceutical control measures were put in place, schools were closed, and warmer weather encouraged more outdoor as opposed to indoor activities. It is possible that environmental conditions such as temperature and relative humidity also could impact transmission. Although virus can be detected on environmental surfaces, evidence favors predominantly respiratory transmission. Infectiousness peaks prior to symptom onset.[151]

Many communities then experienced second waves of infection occurring in the late fall and winter seasons. In part, some of these second waves were associated with relaxing of containment measures. In general, most of these surges took place in populations that did not have high enough background of previous exposure to generate significant population immunity. However, mutations in the viral stalk protein that impact binding to the ACE2 receptor, and that also effect the binding of neutralizing antibody, also have occurred and in some cases resulted in second waves in populations that had already experienced very high incidence rates. Emerging data suggest that these mutant viruses, or variants, may have increased transmissibility and may be associated with increased severity of illness and 20% to 60% increases in the case fatality rate. Antibody generated by infection or vaccination may be significantly less effective at neutralizing some variants, and continued evolution of variants could require strategies for periodic vaccination with updated vaccine components (see below), similar to the strategy used for seasonal influenza.

Pathogenesis of COVID-19 Infection is thought to primarily begin in the respiratory tract and progress to the lower respiratory tract over several days. Virus shedding can be detected prior to the onset of symptoms, and infection in healthy young adults may be largely asymptomatic.[152] As the disease progresses, it is associated with increasing hypoxia and respiratory distress, associated with increases in IL-6 and other inflammatory mediators, referred to as "cytokine storm."[153] Higher concentrations of IL-6 and D-dimer were independently associated with in-hospital mortality.[154] Disease is frequently associated with hypercoagulability with both microangiopathy and local thrombus formation, as well as a systemic coagulation defect that leads to large vessel thrombosis and major thromboembolic complications, including pulmonary embolism in critically ill hospitalized patients.[155]

Treatment and Prevention of COVID Developing effective therapies for COVID-19 that could speed recovery, reduce hospitalization rates, or within hospitalizations reduce ICU admissions and deaths, are a critical public health need. Current recommendations for treatment of COVID-19 are summarized in the IDSA guidelines.[156]

Several strategies have been pursued in this regard. The first has been the well-established approach of developing direct acting antiviral agents that inhibit the replication of the virus. A second approach has been to develop host-directed therapies designed to reduce the inflammatory response that appears to play an important role in the pathogenesis of disease. Because of the urgency of the situation, emphasis has been placed, where possible, on repurposing already existing products and evaluating their potential effectiveness for COVID. A third approach has been the administration of monoclonal antibodies, or antibody cocktails that neutralize virus and speed clearance.

A variety of potentially direct-acting antiviral agents have been evaluated for the treatment of COVID-19, and many studies are still ongoing. Of these agents, remdesivir, an inhibitor of the viral RNA dependent polymerase, has been shown to be beneficial in randomized trials. These studies have demonstrated reduced duration of illness in hospitalized patients.[157] In patients with severe COVID-19 not requiring mechanical ventilation, there were no differences between patients treated with a 5-day course compared to a 10-day course of remdesivir.[158] In another study,[159] hospitalized subjects randomized to 5 days, but not 10 days, of remdesivir had clinical improvement, although significance was unclear.

Other repurposed drugs with potential direct antiviral effects, including hydroxychloroquine and lopinavir, have had little or no effect on hospitalized patients with COVID-19, as indicated by overall mortality, initiation of ventilation, and duration of hospital stay.[160] Generally, studies have not shown benefit of hydroxychloroquine in treatment of hospitalized patients[161,162] or in prevention of disease when administered to exposed patients.[163] More recently, nirmatrelvir/ritonavir (Paxlovid) and molnupiravir have been recommended for nonhospitalized patients at high risk for severe disease (see CDC guidelines at CDC.gov).

Because severe COVID-19 is associated with a prominent inflammatory response and elevated proinflammatory cytokines, there has been considerable interest in repurposing anti-inflammatory agents, many of which are used to treat conditions such as rheumatoid arthritis, for the treatment of severe COVID disease. The most success has been seen with steroids. In patients hospitalized with COVID-19 who require oxygen or mechanical ventilation, the use of dexamethasone has been shown to result in lower 28-day mortality[164] and an increase in the number of ventilator-free days.[165] Severe COVID is also associated with high levels of the proinflammatory cytokine IL-6, but the results of therapy directed at this have been mixed. In hospitalized patients with COVID-19 pneumonia who were not receiving mechanical ventilation, tocilizumab (anti-IL6 receptor antibody) reduced the likelihood of progression to mechanical ventilation or death, but it did not improve survival.[166] Other studies have not shown benefit in treatment of moderate to severe COVID-19 pneumonia[166–169] and might be associated with increased mortality.[170] The Janus kinase inhibitor baricitinib, currently approved for treatment of RA, has been shown to be of benefit when added to remdesivir[171] and is recommended for use in patients who cannot tolerate corticosteroids or have contraindications.

A third approach has been to develop monoclonal antibodies against the spike protein to neutralize CoV-2 and use these in a therapeutic or prophylactic strategy.[172] The utility of prophylactic antibody is limited by the need for intravenous administration and expense. However, a number of monoclonal antibodies or combinations of monoclonal antibodies have been shown to be effective in preventing progression of disease.[173,174] To be effective, monoclonal antibodies should be used relatively early in the course of illness, that is, for treatment of mild to moderate disease in patients who are at risk of progressing to severe or critical disease. Convalescent plasma was not beneficial in hospitalized patients with severe pneumonia.[175]

Vaccines have been developed and deployed. In general, these approaches have been focused on generation of immunity to the spike protein, with an emphasis of generation of neutralizing antibody responses, although other functional antibody and T cell responses also may play a role in protection. Both messenger RNA (mRNA) and adenovirus vector delivery of S antigen have been used internationally, and other platforms including protein subunit and inactivated virion approaches are in development. The ultimate strategies for using such vaccines and best use of future booster doses are currently unknown.

Human Infections with Animal Influenza A Viruses Humans are susceptible to infections with influenza A viruses resident in a variety of animal species, such as swine, horses, and migratory waterfowl. The 2009 pandemic of H1N1, which originated in swine and was due to a virus with a complex genetic makeup of gene segments from human, avian, and swine influenza viruses, is the most recent example of how pandemic influenza arises from animal sources. For this reason, there has been substantial effort put into surveillance for influenza at the animal–human interface, and several small outbreaks of severe disease in humans resulting from transmission of viruses from avian sources have been recognized. The most severe cases have been due to viruses of the H5 or H7 HA subtype, but neither of these viruses has exhibited sustained human-to-human transmission to date.

The available data regarding the signs and symptoms of H5N1 infection are mostly from hospitalized patients.[176,177] Most patients present with the nonspecific complaints of cough and shortness of breath. In many patients, there is a progression of symptoms leading to respiratory failure requiring ventilation and other supportive measures. Atypical symptoms such as nausea, vomiting, encephalopathy, and bleeding gums and nose have been reported. Watery diarrhea may be present prior to the onset of respiratory symptoms. The majority of patients have an abnormal chest x-ray with diffuse and multifocal or patchy infiltration, but pleural effusions are rare.

Aberrant cytokine responses also have been implicated in the pathogenesis of H5N1 disease. Autopsy findings in humans have revealed changes of a reactive hemophagocytic syndrome, ARDS, and multiorgan failure, findings typically associated with production of high levels of cytokines like TNF-α and interferons.

H7 viruses have also caused large outbreaks in humans. In the Netherlands, an outbreak of H7N7 infection associated with a major epidemic in domestic poultry caused numerous human cases.[178,179] Most of these consisted of mild respiratory disease with conjunctivitis, but there was one death from pneumonia. Multiple outbreaks of human H7N9[180] infection have been reported over several years in China. In contrast to previous reports of H7 disease in humans, these outbreaks have been associated with significant lower respiratory tract disease and a mortality rate of approximately 30%. The majority of severe cases have been seen in older adults, many of whom had comorbid conditions.[180,181] It has been suggested that individuals born after 1968, whose first influenza exposure was likely due to H3N2 viruses, might be relatively resistant to H7 viruses because of some shared antigenicity between H3 and H7 viruses.[182] While these outbreaks have not spread widely and sustained person-to-person transmission has not been observed, human infections with novel avian viruses continue to pose a potential pandemic threat.

Hantavirus Pulmonary Syndrome Hantavirus pulmonary syndrome (HPS) was first recognized in the United States in the southwest in 1993 and was discovered to represent transmission from an animal reservoir, the deer mouse, to humans via contaminated rodent feces.[183] Since that time, a variety of hantavirus species have been recognized, and the disease has been diagnosed in both North and South America. Although person-to-person transmission has not been noted in the Northern Hemisphere, the Andes hantavirus has demonstrated such transmission in Argentina and elsewhere.[184]

Clinical features of the Hantavirus pulmonary syndrome (HPS) include onset of severe pulmonary dysfunction after a 2- to 3-day prodrome of nonspecific influenza-like symptoms of fever, myalgias, cough, gastrointestinal symptoms, and headache.[183] Laboratory abnormalities included leukocytosis, increased hematocrit due to hemoconcentration, and thrombocytopenia with coagulopathy.[185] However, clinical bleeding is unusual, in contrast to other systemic Hantavirus syndromes. Moderately elevated levels of serum lactate dehydrogenase and aspartate aminotransferase are typically seen. A variety of radiographic abnormalities have been described. Radiographic findings that may help to distinguish HPS from ARDS include early, prominent interstitial edema and nonperipheral distribution of initial airspace disease.[186]

Presentation of HPS begins with a prodrome of fever, chills, and myalgias, occasionally accompanied by abdominal discomfort and gastrointestinal symptoms, and generalized malaise. Upper respiratory symptoms are usually absent. After a variable period of several days, the patient presents with mild, nonproductive cough and progressive dyspnea resulting from leakage of high-protein edema fluid into the alveoli. On physical exam patients are febrile, with tachypnea and tachycardia with mild hypotension. Examination of the chest may reveal rales but is otherwise unremarkable.

Laboratory studies generally reveal hemoconcentration, mild thrombocytopenia, and mildly elevated lung function tests (LFTs). The triad of thrombocytopenia, left shift with circulating myeloblasts, and circulating immunoblasts is highly suggestive of HPS.[185] Multivariate analysis has identified dizziness, nausea, and the absence of cough as clinical symptoms predictive of HPS, as well as thrombocytopenia, elevated hematocrit, and decreased serum bicarbonate as features that help distinguish HPS from other causes of acute respiratory distress such as pneumococcal pneumonia and influenza.[187] Mild renal abnormalities may be detected, but unlike in hemorrhagic fever with renal syndrome (HFRS), do not progress to renal failure.

Chest radiograph typically shows both interstitial and alveolar infiltrates and resemble noncardiogenic pulmonary edema (Fig. 126-2). Pleural effusions are present in most cases. Early in the course of HPS these effusions are transudative, while later they develop higher fluid protein content and in severe cases have the protein characteristics of plasma. Cardiopulmonary manifestations in severe cases include a shock state with low cardiac index, low stroke volume index, and high systemic vascular resistance. Typically, the pulmonary artery wedge pressure is normal or low. Progression is associated with worsening cardiac dysfunction and development of lactic acidosis. The case-fatality rate averages approximately 30% to 40%. In those patients who survive, recovery is usually complete, but some patients have manifested long-term pulmonary dysfunction. The syndrome in children and adolescents is similar to that in adults.

SUMMARY

Lower respiratory tract viral infections pose an enormous public health burden on both adults and children worldwide. The clinical manifestations, pathogenesis, and laboratory abnormalities of these illnesses are quite variable, and with few exceptions are not specific enough by themselves for etiologic diagnosis. In addition, there is a very wide spectrum of viruses that cause human respiratory illness, with highly variable biology, mutable genomes, and diversity of antigenic characteristics. This wide range of pathogens and highly variable immunology poses substantial challenges to the development of specific medical countermeasures such as antiviral agents and vaccines.

An additional concern is the potential for transmission of previously unknown viral zoonotic pathogens from animals to humans, where they have the potential to spread rapidly and cause catastrophic epidemics and/or worldwide pandemics. There are multiple recent examples of such events, including hantavirus, avian and swine influenza A viruses, and novel coronaviruses. As contacts between animals and humans intensify as a result of population growth and possibly climate change, the potential for transmission of new pathogens will continue to increase.

Public health preparation and response to these events will require continued surveillance in both human and animal populations, international cooperation, and the development of countermeasures that can be very rapidly developed and deployed in response to a pandemic event. Better understanding of the pathogenesis and immunology of viral infection and best strategies for control will ultimately provide pathways forward for improved measures for both pandemic and seasonal respiratory viruses.

CHAPTER 127

Aspiration, Empyema, Lung Abscesses, and Anaerobic Infections

Kyle B. Enfield
Costi D. Sifri

OVERVIEW

Aspiration pneumonia, lung abscess, and necrotic lung are parenchymal lung diseases. *Aspiration pneumonia* refers to the pulmonary consequences that follow abnormal entry of fluid, particulate substances, or endogenous secretions from the upper airways or gastric contents into the lower airways (Chapter 69). Aspiration pneumonia develops following the disruption of a series of formidable host defense mechanisms that normally protect the lower airways. These defenses include, among others: glottic closure via the cricopharyngeus muscle, the cough reflex, and ciliary clearance of the airway. The material aspirated must generate an inflammatory response or cause obstruction. The nature of the pneumonia that develops depends on the inoculum and the host response. Historically, anaerobic bacteria were considered the most common pathogens in this setting, reflecting both pathogenic potential and importance in the normal flora of the upper airways; however, recent data have challenged this view. Risk factors for aspiration may be transient (anesthesia, intoxication) or persistent (e.g., neuromuscular disorders, achalasia). Recurrent aspiration risk depends on recognition and resolution of the inciting defect.[1,2]

Lung abscesses reflect infection with an unusual microbial burden (e.g., acute aspiration), a failure in microbial clearance mechanisms (e.g., bronchial obstruction), or both, leading to necrosis of pulmonary tissue and formation of cavities containing necrotic debris or fluid (Fig. 127-1). The appearance of multiple smaller (<2 cm) abscesses in pulmonary tissue is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are manifestations of the same pathologic processes, and the distinction is arbitrary.[3]

Empyema refers to a purulent collection in any body site but is commonly used to indicate a pleural space infection.[4] Empyema is typically associated with underlying pulmonary parenchymal infection but may also be associated with blood-borne infection, thoracic surgery, trauma, abdominal infection, or neoplasm.[3] Failure to recognize and treat either empyema or lung abscess is associated with a poor clinical outcome.[5,6] In the preantibiotic era, lung abscess was associated with mortality approaching 40%.[7] However, controversy exists over the best approaches to both processes in terms of antimicrobial selection and physical drainage.[5,6]

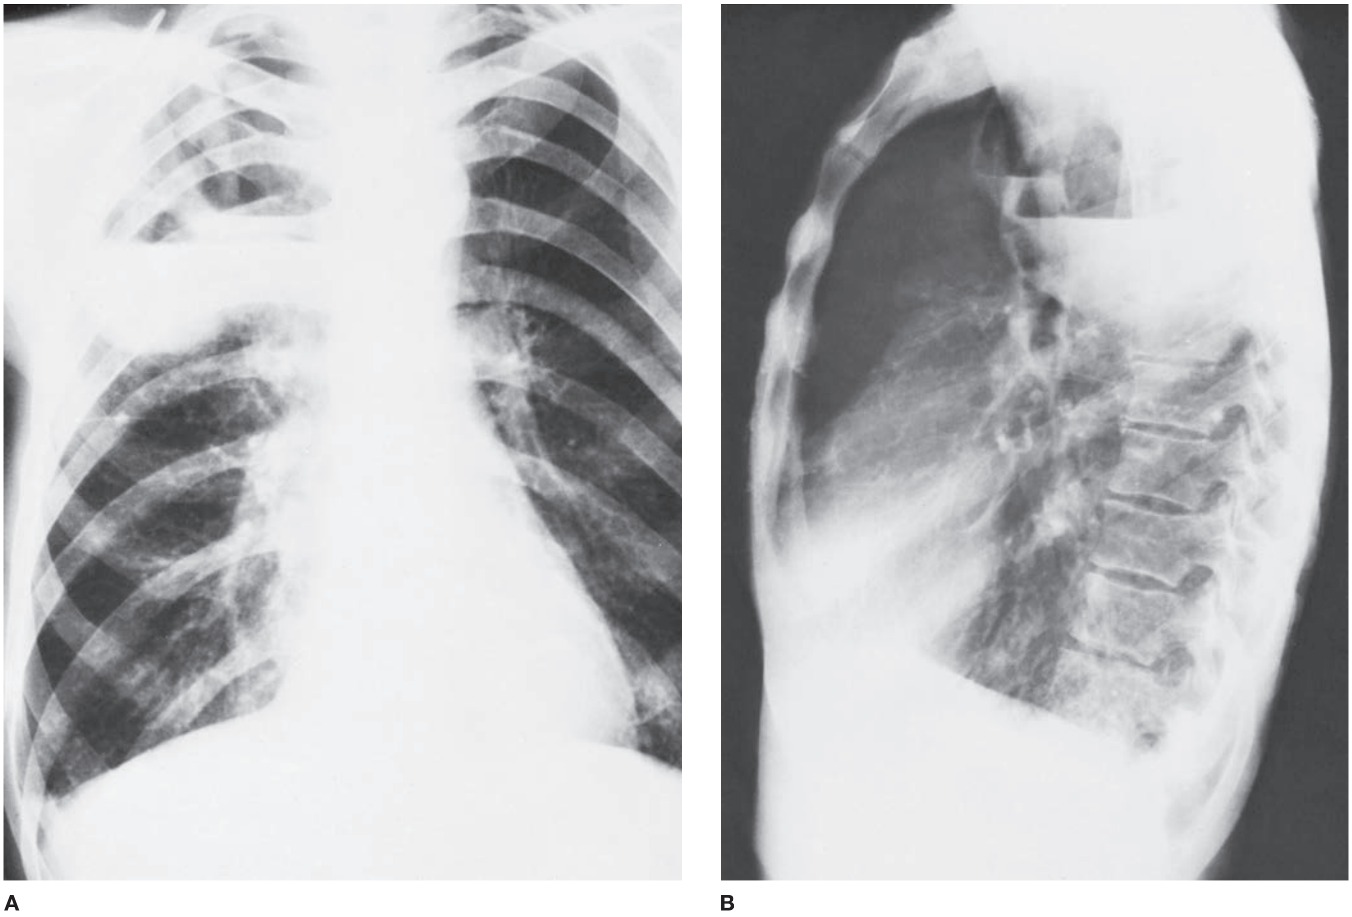

Figure 127-1 **A.** Anaerobic pneumonia with abscess formation in a 48-year-old alcoholic man. The abscesses are located in the posterior segment of right upper lobe, a dependent segment that is seen best on lateral view (**B**).

HISTORY

In 1893, Veillon published a review of "fetid infections," first marking the published record of infections due to anaerobic pathogens. However, anaerobes are now largely forgotten potential pathogens in pulmonary infection, including in both community- and health-care-associated pneumonia.[1] The clinical and bacteriologic features of anaerobic infections of the lung have been documented by extensive studies during two periods of investigation.[1] The first was at the turn of the century when anaerobic bacteria were initially reported as significant causes of empyema. This early work continued through the late 1920s when David Smith conducted classic studies on the pathogenesis of lung abscess. At that time, approximately one-third of patients with lung abscess died. Smith noted that the bacteria in the walls of the abscess at autopsy resembled the bacteria found in the gingival crevice, leading him to conclude that aspiration was the central mechanism in pathogenesis. He subsequently supported this hypothesis by inoculating the trachea of experimental animals with gingival crevice material to reproduce the sequence of pneumonitis events, followed by lung abscess formation in 7 to 10 days.[8,9] Bacteriologic studies of the inoculum showed that four bacterial species were critical, and all were anaerobic bacteria: a fusiform bacterium now recognized as *Fusobacterium nucleatum*, *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), *Peptostreptococcus*, and an anaerobic spirochete. This study is one of the first demonstrations of bacterial synergy, defined as the demonstration that two or more bacterial species are required to produce a pathologic process that could not be reproduced by any single component of the inoculum.[9]

In the first two or three decades of the antibiotic era, the role of anaerobic bacteria in this and other pathologic processes was largely ignored. Patients with lung abscesses often had putrid sputum and no identifiable pathogen; these infections were frequently referred to as nonspecific lung abscesses. Although the microbial cause was unknown, it was well established that these patients almost invariably responded to penicillin treatment. The role of anaerobes in empyema was also largely ignored, which can be ascribed to the paucity of laboratories capable of cultivating oxygen-sensitive bacteria at the time. Studies of anaerobic bacteria were spawned by the ability to culture anaerobes in clinical laboratories with the introduction of anaerobic gas–generating culture jars, the description of the taxonomy of these organisms, and the availability of new antimicrobial agents (clindamycin, metronidazole, cefoxitin) for the therapy. The introduction and widespread use of transtracheal aspiration (TTA) in the late 1960s made it realistic to collect uncontaminated specimens from the lower airways used for anaerobic cultures. TTAs are seldom performed today, so anaerobic bacteria are rarely established as pulmonary pathogens. However, these organisms are important in patients with aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema, and are often suspected based on the etiologic route of infection (e.g., oropharyngeal flora).[1]

PATHOPHYSIOLOGY OF ASPIRATION, EMPYEMA, AND LUNG ABSCESS

The bacteria implicated in anaerobic lung infections represent the normal flora of the oral cavity—primarily the gingival crevice, where anaerobic bacteria are found in concentrations that approach the geometric limits with which bacteria occupy space: 10^{12}/g.[10] Compromised consciousness or dysphagia is the most frequently predisposing risk factor for clinically significant aspiration. Common conditions associated with clinically significant aspiration include alcoholism, general anesthesia, seizure disorder, drug abuse, esophageal lesions, hepatic failure with a decreased level of consciousness, and neurologic deficits associated with dysphagia.[11]

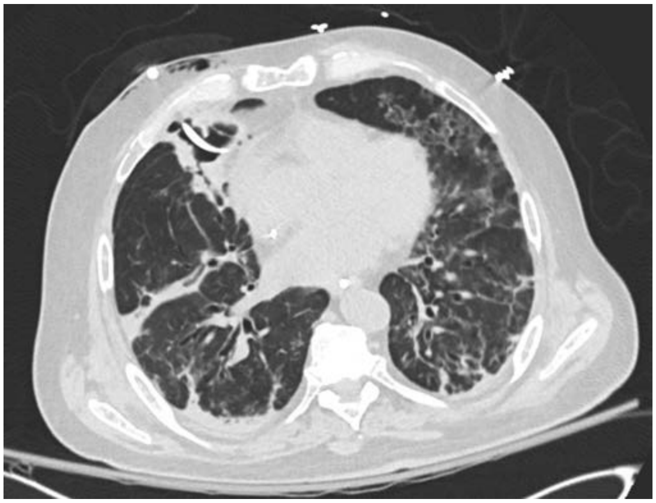

Figure 127-2 An 18-year-old man with COVID-19 pneumonia on ECMO with a bronchopulmonary fistula and polymicrobial empyema (*Escherichia coli*, *Klebsiella pneumoniae*, *Prevotella melaninogenica*, and *Fusobacterium nucleatum*).

Additional conditions that appear to predispose to anaerobic infections include pulmonary infarction, obstruction due to carcinoma or a foreign body, and bronchiectasis. These conditions are associated with stasis or necrosis of tissue, which presumably accounts for the association with anaerobic infections. The use of acid-suppressing medication has also been associated with community-acquired, hospital-acquired, and ventilator-associated pneumonia, presumably due to loss of the gastric acid barrier to bacterial growth.[12,13]

A somewhat unique feature of anaerobic lung infections is the proclivity for necrosis of tissue, resulting in abscess formation of a bronchopleural fistula associated with empyema (Fig. 127-2).[14] Virulence factors of anaerobic bacteria presumed to account for this association include the capsular polysaccharide of anaerobic Gram-negative bacilli. The most extensively studied is the polysaccharide of *Bacteroides fragilis*; however, the same observations may also apply to *P. melaninogenica* and other anaerobic Gram-negative bacilli.[15–17] The capsule of *B. fragilis* consists of a family of polysaccharides composed of oligosaccharide repeating units with sugars containing positively charged free amino groups and negatively charged carboxyl, phosphate, and amino groups.[16–19] These positive and negative charges mediate the capacity to induce abscess formation in experimental animals.[19,20] Another virulence factor possessed by most anaerobic bacteria is the production of short-chain fatty acids that inhibit phagocytic killing at low pH levels.[21,22] Short-chain volatile fatty acids are metabolic products of anaerobic bacteria used to classify these organisms taxonomically. They appear to be responsible for the putrid odor that is often a characteristic feature of infections by these organisms.[23,24]

MICROBIOLOGY

Bacteriologic findings of anaerobic lung infections from two large series are summarized in Table 127-1. Most of these infections involve multiple bacterial species, and approximately half of the patients have anaerobic bacteria combined with potentially pathogenic aerobic or facultative anaerobes. Community-acquired infections involving only anaerobes and those with mixtures of aerobic and anaerobic bacteria show common clinical features and no difference in the frequency of suspected aspiration, indolent presentation, or putrid discharge. The implication is that a putrid lung

abscess with *Escherichia coli* in expectorated sputum, or anaerobic bacteria plus *E. coli* in a TTA, should usually be considered an anaerobic infection. However, caution is advised in applying these conclusions to nosocomial pulmonary infections since this is a setting in which the aerobic component of the infection is probably more important.

The establishment of anaerobic bacteria in pulmonary infections requires specimens of respiratory secretions devoid of contamination from the upper airways. Procedures satisfying this criterion are TTA, transthoracic aspiration, open lung biopsy, thoracentesis, and, more recently, bronchoscopy with quantitative cultures. In addition, there must be appropriate laboratory expertise for the cultivation of anaerobic bacteria. The incidence of anaerobic lung infections reported in published studies from the antibiotic era that satisfy both requirements is summarized in Table 127-2.

Most historic reports examining the role of anaerobic bacteria in aspiration pneumonia or lung abscess demonstrated recovery rates ranging from 62% to 100%. The typical specimens in these studies were collected by TTA and transthoracic aspiration. For example, in a study published in 1965, Beerens and Tahon-Castel[25] used transthoracic needle aspiration to characterize the flora in lung abscesses; this series showed recovery of anaerobic bacteria, usually in pure culture, in 22 (85%) of 26 cases. The major bacterial isolates in patients with anaerobic lung infections are *Peptostreptococcus*, *F. nucleatum*, and *P. melaninogenica*, often with concomitant aerobic and microaerophilic streptococci.

More recent studies, however, have shown a shift from anaerobes to bacterial pathogens typically associated with community-acquired and hospital-acquired pneumonia.[26] Indeed, modern studies have shown that anaerobic bacteria are recovered in a small minority of cases of aspiration pneumonia.[26–28] The reason for this discrepancy is not clear but could reflect that historically TTA was often performed late in the course of illness, often after patients developed complications such as lung abscess or empyema, or differences in patient characteristics in older studies, such as higher representations of chronic alcoholism.[26] Furthermore, improvement in oral health, which is associated with respiratory health, may influence the incidence of anaerobic pneumonia.[29]

There have been few studies to identify the frequency of anaerobic bacteria in unselected cases of community-acquired pneumonia. Ries et al.[30] performed TTAs in patients hospitalized with a diagnosis of pneumonia and recovered anaerobic bacteria in 29 (33%) of 89 cases. A more recent study by Pollock et al.,[31] using fiberoptic bronchoscopy with a protected catheter and quantitative cultures, showed recovery of anaerobes in 16 (22%) of 74 patients. These two reports suggest that anaerobic bacteria are relatively common pathogens among patients with community-acquired pneumonia and presumably account for a substantial proportion of cases that are considered enigmatic. In nosocomial pneumonia, Bartlett et al.[32] utilized TTA in 159 consecutive patients and showed anaerobes in 56 (35%). Nevertheless, most of these patients also showed the simultaneous presence of aerobic gram-negative bacilli or *Staphylococcus aureus*, and their clinical course was determined largely by the aerobic pathogens.

TABLE 127-3 Clinical Features of Anaerobic Pulmonary Infections[a]

	Lung Abscess (83 pts)	Empyema (51 pts)	Pneumonitis (only) (79 pts)	Total (193 (pts)
Age (median, years)	52	49	60	51
Peak temperature (mean, °F)	102.1	102.4	102.6	102.4
Peripheral leukocyte count (median/mm)	15,000	21,600	13,700	15,000
History of weight loss	36 (43%)	28 (55%)	3 (4%)	57 (30%)
Putrid discharge	41 (49%)	32 (63%)	4 (5%)	62 (32%)
Lethal outcome	3 (4%)	3 (6%)	3 (4%)	8 (4%)

[a] *Based on retrospective chart review of 193 cases established by recovery of anaerobes as dominant flora in TTA, pleural fluid, or blood culture.*

Data from Bartlett JG. Anaerobic bacterial infections of the lung. Chest. 1987;91:901–909; Bartlett JG. Anaerobic bacterial infections of the lung and pleural space. Clin Infect Dis. 1993;16:S248–S255; Marina M, Strong CA, Civen R, et al. Bacteriology of anaerobic pleuropulmonary infections: preliminary report. Clin Infect Dis. 1993;16: S256–S262.

CLINICAL FEATURES

Nearly all patients with anaerobic lung infections have the usual constitutional findings for patients with infection (Table 127-3). A review of 193 bacteriologically confirmed cases showed that the mean peak temperature for hospitalized patients was 39.1°C and all but 5 patients were febrile. The average peripheral leukocyte count was 15,000/mL[3]. Patients presenting with suppurative complications had a longer duration of symptoms before presentation; this was commonly associated with other evidence of chronic disease, including weight loss and anemia. Another common feature of patients with suppurative complications was putrid sputum or empyema fluid, which was noted in 40% to 60%. It should be emphasized that the putrid discharge in these cases is considered diagnostic of anaerobic infection since aerobic bacteria are not capable of producing this characteristic odor either in vitro or in vivo. Thus, anaerobic bacteria may cause a diverse range of pulmonary infections, which may be acute, subacute, or chronic. The anaerobic etiology is rarely established or even suspected in patients with acute pneumonitis. This compares with aspiration pneumonia, where anaerobes are presumed pathogens in most community-acquired infections and may contribute to many nosocomial cases. By contrast, anaerobic bacteria are readily recognized as potential pathogens in patients with late suppurative complications, such as lung abscess or empyema.

One review of 46 patients with anaerobic bacterial pneumonitis showed similar clinical features to those of pneumococcal pneumonia.[33] The diagnosis was established by TTA, and the results in this group were compared with those in the second group of patients in whom TTAs yielded *Streptococcus pneumoniae*. The two groups were similar in age, changes on the chest radiograph, peak temperature, and peripheral leukocyte count. Significant differences in the group with anaerobic infections were the lack of rigors, somewhat more prolonged duration of symptoms before presentation, and a more frequent association with predisposing conditions for aspiration.[33] An important point to emphasize is that patients presenting in this early stage of infection rarely have the features commonly associated with anaerobic lung infections, such as putrid sputum, tissue necrosis with abscess formation, or a chronic course. These infections presumably account for some and possibly many cases of community-acquired pneumonia in which no etiologic diagnosis is established despite extensive study; such cases account for 40% to 50% of cases in most series. Features of anaerobic infections that are nearly unique are the association with conditions that predispose to aspiration and infection in the gingival crevice, putrid discharge, and a high frequency of suppurative complications in late-stage disease.

ASPIRATION SYNDROMES

Aspiration is a relatively common event that is typically well-tolerated. Numerous studies indicate that virtually all healthy persons aspirate but that this is usually inconsequential. In one study, airway protective mechanisms were challenged by placing contrast material in the mouths of sleeping patients. The following morning, most patients had radiographic evidence of aspiration, defined as contrast material seen on imaging of the lungs, but no evidence of a disease process.[34] Similarly, dye markers placed in the stomach of postoperative patients have later been aspirated from the tracheobronchial tree, indicating aspiration of gastric contents during general anesthesia in 7% to 16%.[35,36] Scintigraphic methods have also been used to demonstrate frequent aspiration in patients with intubation of the airways or gastrointestinal tract.[37–39] None of these studies, however, has shown any clinical consequences from occult aspiration. The conclusion is that aspiration is relatively common but usually resolves spontaneously. The decisive factor for the development of lung complications depends on the frequency, volume, and character of the material in the inoculum. The aspiration of large volume or frequent aspirations leads to three distinct syndromes according to the nature of the inoculum: chemical pneumonitis, bacterial infection, and airway obstruction. The nature of the inoculum also dictates the pathogenesis of pulmonary complications, clinical presentation, and management strategies (Table 127-4).

■ Chemical Pneumonitis

Chemical pneumonitis refers to the aspiration of an inoculum that is inherently toxic to the lungs. Examples include acid, fats such as milk or mineral oil, and volatile hydrocarbons. These substances are toxic to the lower airways and initiate an inflammatory reaction. The effect of acid on the lungs was initially described in animal studies in World War I and subsequently confirmed in humans by Mendelson. His work was the first to describe gastric acid pneumonitis leading to chemical pneumonitis in humans, which came to be referred to as Mendelson syndrome.[39] This is a severe pneumonitis with fever, hypoxia, and respiratory alkalosis, which typically clears rapidly in healthy hosts within 4 to 7 days but may progress following lung injury and superinfection to pneumonia, lung abscess, or acute respiratory distress syndrome (ARDS) (Chapters 140 and 141). Factors that contribute to hypoxemia are pulmonary edema, reduced surfactant activity, reflex airway closure, hyaline membrane formation, and alveolar hemorrhage. Pulmonary function tests show decreased compliance, abnormal ventilation–perfusion, and reduced diffusing capacity.[2] The pathophysiology of gastric acid pneumonitis has been studied in experimental animals with intratracheal instillation of graded acid inocula. This work shows that the pH must be 2.5 or less, and a relatively large inoculum, usually a minimum of 0.3 to 0.6 mL/kg, is required for the inflammatory process to be initiated.[40–43] It is possible that smaller volumes create a less dramatic presentation or may go undetected.[41,43] Support for this hypothesis is the observation of frequent

TABLE 127-4 Classification of Aspiration Pneumonia

Inoculum	Pulmonary Sequelae	Clinical Features	Therapy
Acid breathing	Chemical pneumonitis	Acute dyspnea, tachypnea; tachycardia; cyanosis, bronchospasm, fever Sputum: pink, frothy Radiographic infiltrates in one or both lower lobes Hypoxemia	Supplemental oxygen, bronchodilators, mechanical ventilation as needed
Oropharyngeal bacteria	Bacterial infection	Usually insidious onset Cough, fever, purulent sputum Radiographic infiltrate in dependent pulmonary segment or lobe ± cavitation	Antibiotics
Inert fluids	Mechanical obstruction Reflex airway closure	Acute dyspnea, cyanosis ± apnea Pulmonary edema	Tracheal suctioning, supplemental oxygen, mechanical ventilation as needed
Particulates	Mechanical obstruction	Dependent on level of obstruction, ranging from acute apnea and rapid death to irritating chronic cough ± recurrent superimposed infections	Extraction of matter Antibiotics for infection

bouts of pneumonitis and otherwise unexplained pulmonary fibrosis in patients with gastric reflux or esophageal disease.[44,45]

Pathologic changes in acid pneumonia occur rapidly. Atelectasis occurs within seconds and is extensive within minutes. There is also peribronchial hemorrhage, pulmonary edema, and bronchial epithelial cell degeneration. The alveolar spaces fill with neutrophils within hours, and hyaline membranes are seen within 48 h. Resolution begins by the third day and may be complete or may result in residual scarring of the pulmonary parenchyma.[46,47] Long-term follow-up studies in patients who have gastric acid pneumonia show either complete recovery or radiographic evidence of pulmonary fibrosis with abnormal gas exchange.[48,49] Pulmonary fibrosis may also be associated with repeated, small, “silent” aspirations of gastric secretions without clinically overt pneumonitis (Chapters 56 and 57).[44,50]

The diagnosis of acid pneumonia is usually presumed on the basis of clinical observations such as the abrupt onset of dyspnea in a patient who is aspiration prone and has radiographic evidence of infiltrates, usually in the lower lobes. Other characteristic clinical features are the rapid clearing of the infiltrates and progression to ARDS.[47,51] Bronchoscopy demonstrates erythema of the bronchi, suggesting a “chemical burn.”[52] Confirmation of the acid inoculum is not possible because of rapid neutralization by pulmonary edema fluid and bronchial secretions within minutes after aspiration.

The treatment of gastric acid aspiration includes tracheal suction to clear fluids and particulate matter that may have been concurrently aspirated. Supportive care consists primarily of ventilatory support with positive-pressure ventilation and resuscitation with intravenous fluids.[47,53] While use of corticosteroids dates back to the 1950s, clinical trials have not shown them to be beneficial.[54–56] Use of prophylactic antimicrobial agents for acute aspiration pneumonitis has not been shown to reduce ICU transfer or mortality but is associated with escalation of antimicrobial treatment for those who develop pneumonia.[57,58] Supportive treatment is the mainstay, and antimicrobial therapy should be reserved for those with superinfection.

■ Aspiration Pneumonia

While not as fulminant as chemical pneumonitis,[59] bacterial infection following aspiration is associated with an increased risk of prolonged hospitalization and death.[60,61] In the preantibiotic era, the natural history of these infections could be followed. The initial presentation was similar to chemical pneumonitis, usually combined with purulent sputum. After 8 to 14 days, progression to tissue necrosis with abscess formation or extension into the pleural space may occur. This stage is marked by putrid discharge and cavitation.[62–64] The distinction between aspiration pneumonia and other forms of pneumonia is based mainly on the clinical characteristics, but clear overlaps exist. For example, healthy elderly patients with community-acquired pneumonia have a markedly higher incidence of silent aspiration than matched control patients.[65] While no gold standard for the diagnosis of aspiration exists, studies suggest that 5% to 15% of community-acquired pneumonia may be due to aspiration.[11,66,67] The incidence of aspiration pneumonia in elderly patients with community-acquired pneumonia may be much higher.[68,69] The diagnosis of aspiration pneumonia is often inferred from patient characteristics. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum, and patients with necrotizing pneumonia or lung abscess on chest radiograph.[26,47,70,71]

■ Mechanical Obstruction

Aspiration may involve fluid or particulate material. In this form of aspiration pneumonia, the inoculum is not toxic to the lung but may cause obstruction or reflux airway closure. In most cases, there is only transient, self-limited hypoxemia due to rapid clearance.[46] Some patients develop pulmonary edema, with hypoxemia and reduced compliance apparently due to an intrinsic pulmonary reflex closure.[46] Other patients suffer sequelae due to failure to clear relatively large volumes of the aspirate, such as near-drowning victims and patients with profound neurologic deficits or coma. The apparent critical intervention is tracheal suction.

Aspiration with mechanical obstruction may also be associated with solid particles. Foreign-body aspiration is most frequent in children 1 to 3 years of age.[72–74] The most common objects in the lower airways are vegetable particles, inorganic materials, and teeth.[72–74] The severity of the obstruction depends on the relative size of the material aspirated and the caliber of the lower airways. Large objects may cause obstruction at the level of the larynx or trachea, leading to sudden respiratory distress, cyanosis, stridor, and in some cases, aphonia.[75,76] This is referred to as café coronary syndrome because it often involves meat aspiration during restaurant dining and may simulate an acute myocardial infarction.[77] Aspiration of smaller particles may result in complete obstruction of more distant components of the tracheobronchial tree or partial obstruction. Chest radiographs often show atelectasis or obstructive emphysema.[78] Common symptoms include chronic cough, fever, hemoptysis, and dyspnea.[79,80] An essential clue in some cases is unilateral wheezing.[81] Bacterial infection is not present in the early stages of obstruction but is a common feature when obstruction has been present for more than 1 week.[82] The most common pathogens are anaerobic bacteria from the upper airways. These patients may respond well to antibiotics but often have recurrent infections in the same pulmonary segment.[72] The most important therapeutic intervention is removal of the foreign body, usually with bronchoscopy.[73]

Radiologic Diagnosis

Chest radiographs in patients with anaerobic lung infections typically demonstrate infiltrates (with or without cavitation) involving dependent pulmonary segments.[1,47] The favored locations are the superior segment of the lower lobes or posterior segments of the upper lobes—dependent segments in the recumbent position. The basilar segments of the lower lobes are favored in patients who aspirate in the upright position. The right lung is more frequently affected owing to the more direct takeoff of the right mainstem bronchus.

Laboratory Diagnosis

Aspiration pneumonitis is a clinical diagnosis. It is generally assumed that there is an anaerobic component to pneumonia in patients with altered consciousness or after surgical procedures. It is important to emphasize the utility of the Gram stain in making the diagnosis of anaerobic lung infection. Often culture data are not available to confirm the presence of these organisms. However, most anaerobic Gram-negative bacteria have unique morphologic features that make them relatively easy to identify or suspect on direct Gram stain. For example, peptostreptococci appear like their aerobic counterparts. Aspiration pneumonia is usually a mixed infection involving multiple bacteria; about half of the cases demonstrate mixtures of aerobic and anaerobic bacteria.[1,83,84] Thus, the detection of polymicrobial flora or bacteria with the unique morphology of anaerobes on any specimen that is devoid of contamination by normal flora represents an important clue to the probable presence of anaerobic infection.

Determination of the microbiology of anaerobic infections of the lower airways requires a specimen devoid of contamination by the flora of the upper airways or quantitative cultures that distinguish pathogens from normal flora. Uncontaminated specimens that are considered valid for anaerobic culture include pleural fluid, TTAs, transthoracic aspirates, and specimens obtained at thoracotomy or thoracoscopy. Quantitative cultures of specimens obtained at fiberoptic bronchoscopy, either by BAL or with the protected brush, also may be used for this purpose.[1] Anaerobic bacteriology should not be obtained from standard bronchoscopic aspirates. Quantitative culture of lower airway secretions improves diagnostic accuracy with virtually any specimen that is subject to contamination, including expectorated sputum and tracheostomy aspirates. Most studies employing these techniques have used them to detect aerobic bacteria; relatively few studies evaluated anaerobic cultures. Whether treatment decisions based on quantitative cultures of anaerobic pathogens improve treatment outcomes is unknown.

When possible, respiratory samples should be obtained before the inception of antibiotic treatment. In clinical practice, specimens are often not obtained for anaerobic culture until the patient has developed complications of persistent infection, which significantly reduces their yield. Thus, the anaerobic pathogens should be considered in the appropriate clinical context, even when only aerobic organisms are isolated.

It is essential that material obtained for culture be placed under anaerobic conditions promptly before transport to the laboratory. A sealed syringe provides the best container, with delivery of the specimen to the laboratory within 20 to 30 min for immediate plating. It is imperative that air bubbles be eliminated from the syringe and needle. Special anaerobic transport tubes are available for brush or liquid specimens. It is important to obtain additional pulmonary specimens for culture and antibiotic susceptibility measurements from patients failing to respond to initial therapy (Fig. 127-3). Such data may demonstrate the presence of unrecognized or antibiotic-resistant organisms. Most of these infections are polymicrobial, and many of the organisms grow slowly in vitro. Thus, it often takes several days to separate, identify, and report results of anaerobic cultures. There is great variation in the availability and quality of in vitro susceptibility tests. These factors illustrate the need for empiric decisions regarding antibiotic selection.

Prevention

The reversibility of underlying conditions predisposing to aspiration must be considered. It has recently been recognized, for example, that aspiration in lung transplant recipients is a major predisposing factor to graft injury and obliterative bronchiolitis.[85] In the general patient population, nasogastric feeding tubes, sedation, lying flat in bed while sleeping, reflux, and frequent choking are associated with aspiration and should suggest strategies for remediation.[47] Gastric surgery for obesity also has been associated with a high incidence of aspiration disease.[86]

Positioning, dietary changes, medications, oral hygiene, antiseptic oral rinses, and tube feeding, among other interventions, have been proposed to prevent aspiration in both hospitalized and nonhospitalized patients, particularly in the elderly. However, studies have failed to support specific intervention in the outpatient setting.[87] While using nectar or honey-thickened liquids decreases aspiration among patients with dementia or Parkinson disease,[88] the incidence of pneumonia is not changed.[89] Studies have also failed to demonstrate that aspiration prevention measures improved outcomes in elderly long-term care residents. In a large, multicenter study involving 36 nursing homes, the combination of oral hygiene care, semirecumbent position when eating, and chlorhexidine gluconate oral rinses had no impact on the incidence of pneumonia or the overall mortality rate.[90]

Methods to prevent aspiration have been studied most extensively in hospitalized patients, especially in those who are aspiration prone. Most important is use of semirecumbent or upright positioning.[91] Additional measures to prevent aspiration with variable efficacy include tracheostomy, reducing gastric contents by suction or metoclopramide, feeding via gastrostomy tube, and neutralization of gastric acid. Many of these procedures may alter colonization patterns and potentially may predispose to more significant infections. Neutralization of gastric acid may increase colonization of the oropharynx and thereby increase the risk of bacterial infection following aspiration of gastric contents. Tracheostomy is useful in some patients with repeated aspiration, but inflation of the balloon may occlude the esophagus and promote aspiration of upper airway contents. Patients who require nasogastric feedings are aspiration prone; percutaneous endoscopic gastroscopy (PEG) may be an alternative method to address this issue, but study results are quite variable. A recent meta-analysis of nine studies found that while PEG feeding was superior to nasogastric tube feeding in providing consistent nutritional support, the incidence of pneumonia was no different between the two groups.[92] Alternative procedures sometimes considered to prevent or limit aspiration include post-pyloric feeding jejunostomy and Nissen fundoplication. The use of intermittent oroesophageal (IOE) tube feeding has in a single-center trial shown a reduction in aspiration pneumonia compared with traditional continuous nasogastric tube feeding (16% vs. 31%). In IOE tube feeding, a tube is inserted orally into the esophagus at each

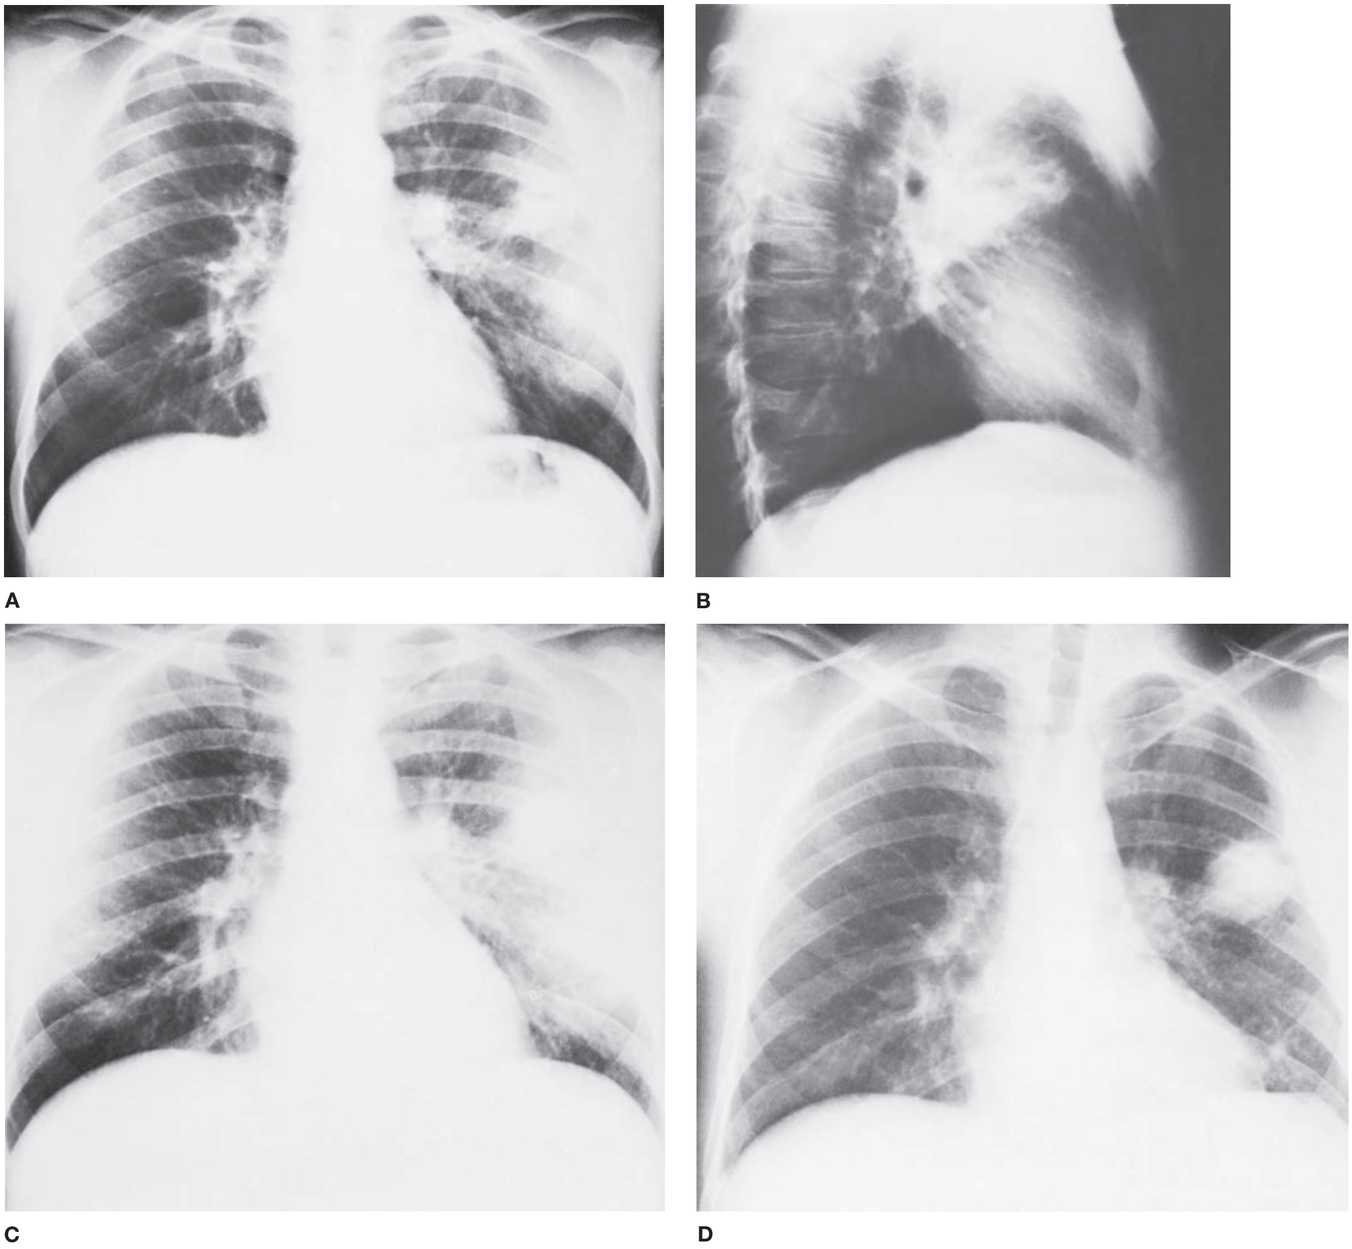

Figure 127-3 Failure of penicillin therapy for anaerobic lung abscess in a 29-year-old alcoholic man. **A.** Admission chest radiograph reveals a radiolucent area within a zone of consolidation in the left upper lung field. **B.** Lateral view demonstrates multiple cavities. The patient was treated for 5 days with penicillin (6 million units per day intravenously), followed by the same dosage orally for 10 days. **C.** Radiographic infiltrate persists, but no cavity is visible. **D.** Six weeks after the cessation of penicillin therapy, the abscess has recurred in the same area. Marked pleural reaction is noted in the vicinity of the recurrent disease.

feeding and then removed. The decrease in pneumonia is hypothetically from a reduction in the interruption of the gastroesophageal sphincter reducing reflux.[93]

Antimicrobial Therapy

It is essential, whenever possible, to obtain microbiologic samples from the lungs and blood in advance of antimicrobial therapy. As for all pneumonias, inappropriate initial therapy has an adverse impact on outcome. The initial choice of antimicrobial agents should be guided by the Gram stain and the likely bacteriology of the infection and then adjusted as culture data become available. The history and a review of previous culture results may be useful in the selection of specific antibiotics. The standard drug historically for aspiration pneumonia and lung abscess involving anaerobic bacteria has been penicillin, usually given intravenously or with high-dose oral treatment. However, in the face of increasing penicillin resistance among *S. pneumoniae* and in 40% to 60% of strains of fusobacteria and *P. melaninogenica* as well as anaerobic Gram-negative bacilli, alternatives should be considered for empiric therapy. In early therapeutic trials in patients with lung abscess involving anaerobic bacteria (Table 127-5), clindamycin proved superior to penicillin in terms of response rates and time to defervescence. Alternative regimens that have been used successfully based on anecdotal experience include amoxicillin-clavulanate and penicillin combined with metronidazole. Metronidazole should not be used as a single agent in patients with anaerobic lung infections since there is a poor response in about 50%.[94,95] The presumed explanation is the contributing role of aerobic and microaerophilic streptococci, which are resistant to this drug.

Many other antimicrobial agents are likely to be useful in anaerobic or mixed aerobic–anaerobic infections: combinations

TABLE 127-5 Antibiotic Treatment of Anaerobic Lung Infections: Results of Two Randomized Trials

Source	Treatment	# Pts	Number of Patients with Failure	Number of Patients with Relapse	Mean Days to Symptom Resolution Fever	Mean Days to Symptom Resolution Putrid Sputum
Levinson (1983)	Penicillin (6 million units/d)	21	5 (29%)	3 (19%)	7.7	7.8
	Clindamycin (1.8 g/d)	17	0[a]	0	4.7[a]	4.1[a]
Gudiol (1990)	Penicillin (12 million units/d)	18	7 (39%)	2 (11%)	7.2	7.3
	Clindamycin (2.4 g/d)	19	1 (5%)	0	6.4	3.9[a]

[a] *Difference for treatment favoring clindamycin is statistically significant.*

of a β-lactam and β-lactamase inhibitor (ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam), carbapenems (ertapenem, imipenem-cilastatin, meropenem), and second-generation cephalosporins such as cefoxitin or cefotetan. Macrolides (erythromycin, clarithromycin, and azithromycin) offer good in vitro activity against most species except fusobacteria. Oxacillin and nafcillin are much less active. Vancomycin is active only against Gram-positive anaerobes. Drugs that have virtually no activity against anaerobes include aminoglycosides, first-generation fluoroquinolones, aztreonam, and trimethoprim-sulfamethoxazole (TMP-SMX). Moxifloxacin has broad coverage that includes anaerobes;[96] however, increasing resistance in *Bacteroides* spp. raises concerns for the suitability of moxifloxacin monotherapy.[97]

Several new antimicrobial agents may be useful for patients with mixed aerobic-anaerobic pulmonary infections involving multidrug-resistant Gram-negative pathogens, such as carbapenem-resistant *Enterobacterales* (CRE) and extensively drug-resistant (XDR) *Pseudomonas aeruginosa*. The novel siderophore cephalosporin cefiderocol and two new cephalosporin β-lactamase inhibitor combinations, ceftazidime-avibactam and ceftolozane-tazobactam, demonstrate excellent in vitro activity against multidrug-resistant Gram-negative bacilli and have received FDA approval for hospital-acquired bacterial pneumonia (HABP) and ventilator-associated bacterial pneumonia (VABP). Ceftolozane-tazobactam—the combination of a novel, semisynthetic cephalosporin and an established β-lactamase inhibitor—demonstrates enhanced activity against strains of XDR *P. aeruginosa* as well as some extended-spectrum β-lactamase (ESBL)-producing Enterobacteriaceae. The addition of avibactam, a non-β-lactam β-lactamase inhibitor, to ceftazidime restores ceftazidime activity against Gram-negative bacteria that produce serine class A or class D carbapenemases, such as *Klebsiella pneumoniae* carbapenemase (KPC) or the oxacillinase OXA-48, respectively.[98] Cefiderocol is a novel siderophore cephalosporin with a spectrum of activity that includes CRE, XDR *P. aeruginosa*, and several other highly drug-resistant Gram-negative pathogens, including *Stenotrophomonas maltophilia*, *Acinetobacter baumannii*, and *Burkholderia cepacia*.[99] However, all three have limited anaerobic activity. The addition of metronidazole is recommended when using these agents to treat nosocomial pneumonia due to both anaerobes and multidrug-resistant Gram-negative pathogens.

Two new carbapenem β-lactamase inhibitor drug combinations offer additional treatment options for patients with HABP/VABP due to a combination of anaerobic and extensively drug-resistant Gram-negative bacteria. Meropenem-vaborbactam, a carbapenem and novel cyclic boronic acid–based β-lactamase inhibitor drug combination, has received FDA approval for the treatment of complicated urinary tract infections including those caused by CRE. Given its spectrum of activity and limited clinical trial experience, meropenem-vaborbactam is predicted to be a therapeutic option for mixed aerobic–anaerobic pulmonary infections involving CRE.[100,101] However, the addition of vaborbactam to meropenem does not improve activity against *P. aeruginosa* compared with meropenem alone and therefore should not be used to treat pneumonias involving carbapenem-nonsusceptible *P. aeurinosa*.[102]

Another novel carbapenem β-lactamase drug combination, imipenem-cilastatin-relebactam, was recently approved by the FDA to treat HABP/VABP involving pathogens multidrug-resistant pathogens. Relebactam is a novel β-lactamase inhibitor that inhibits Ambler class A serine carbapenemases, including *K. pneumoniae* carbapenemase (KPC). Furthermore, relebactam can increase activity of imipenem against imipenem-nonsusceptible *P. aeruginosa*. For mixed pulmonary infections that include MDR Gram-negative bacteria like KPC-producing CRE and anaerobes, imipenem-cilastatin-relebactam may be a new option in the antibiotic armamentarium.[103]

While first-generation tetracyclines show limited activity against many anaerobic bacteria in vitro, the tetracycline analogues tigecycline (a glycylcycline) and eravacycline (a fluorocycline) have broad-spectrum antimicrobial activity against Gram-positive, Gram-negative (except *P. aeruginosa*), and anaerobic bacteria. Both have been approved by the FDA for the treatment of complicated intra-abdominal infections, and tigecycline has an approved indication for the treatment of community-acquired pneumonia due to *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Legionella pneumophila*. However, tigecycline has an FDA boxed warning against use for HABP/VABP due to increased risk of death compared with other antibiotics.[104] Correspondingly, experience with eravacycline for the treatment of healthcare-associated or aspiration pneumonia is limited and its role remains to be determined.

The appropriate duration of therapy is unclear. No clinical trials have been performed to determine optimal treatment term. Typically the duration is dependent on the clinical and radiographic response of the patient. Patients should be treated at least until fever, putrid sputum, and abscess fluid have resolved, and any fluid collections have resolved or stabilized, typically over 2 to 3 weeks. In the absence of abscess formation, a course of 7 to 10 days of antibiotics is recommended, but longer courses may be necessary. Relapse is common and may involve organisms resistant to initial antibiotic agents (Fig. 127-3).

LUNG ABSCESS

Because the most important predisposing condition for lung abscess is aspiration, lung abscesses are most often located in the posterior segment of the right upper lobe, less often in the left upper lobe, and the apical segments of the lower lobes (Fig. 127-1). Periodontal disease is highly associated with lung abscess formation; in edentulous patients, lung abscesses are uncommon and may suggest the presence of an obstructing lesion of the bronchus, pulmonary embolus, septic embolus, or unsuspected pathogen. Nosocomial aspiration often involves Gram-negative bacteria, particularly organisms with hospital-acquired antibiotic resistance patterns. Many of these infections progress to suppurative complications, with presentation as lung abscess or empyema. Usually 1 to 2 weeks are required for cavity formation.

Lung abscesses generally develop after inflammation produces tissue necrosis with cavitation. In the presence of pre-existing cavitary disease, for example, due to emphysema or old tuberculous lesions, infection may proceed without frank necrosis. The abscess cavity may become lined with regenerated epithelium. Local obstruction may produce bronchiectasis or emphysema in the surrounding lung.

The classification of lung abscesses is based on the duration and likely cause of the process. Acute abscesses are less than 4 to 6 weeks old, whereas chronic abscesses are of greater duration. Primary abscesses are infections due to aspiration or to pneumonia in the normal host; secondary abscesses are due to pre-existing conditions (obstruction, spread from an extrapulmonary site, bronchiectasis, immune compromise). Abscesses with foul odors associated with anaerobic organisms are often called putrid abscesses.

■ Microbiology

In lung abscesses, anaerobes are recoverable from up to 93% of patients.[14,15] In some patients, anaerobic organisms of presumably greater virulence (e.g., *Fusobacterium* or *Peptostreptococcus*) may be found as the sole infecting organism. In studies by Bartlett and Finegold,[3] 46% of patients with lung abscesses had only anaerobes isolated in cultures, while an additional 43% had a mixture of anaerobes and aerobic bacteria. In addition to anaerobes, among the organisms often implicated in lung abscess formation or in necrotizing pneumonia included are *S. aureus*, *Streptococcus pyogenes*, *K. pneumoniae*, and *P. aeruginosa*. Infrequently, other Gram-negative bacilli, such as *E. coli* and *H. influenzae* type B, may cause pulmonary necrosis. Uncommon but important causes of cavitating pneumonia are *Nocardia* spp., *Paragonimus westermani*, *Legionella* species, *Burkholderia pseudomallei*, *Burkholderia mallei* (glanders), and tuberculosis. Certain fungal infections may cause cavitation in diabetic and immunocompromised hosts (e.g., the Mucoraceae, *Aspergillus* species). *Entamoeba histolytica* is an important but uncommon cause of lung abscess, almost always in the basilar portion of the right lower lobe.

■ Clinical Features

The clinical presentation of lung abscess may be coincident with the initial presentation of pneumonia or other underlying condition or may occur later in the clinical course. Suspicion may be heightened by the presence of conditions predisposing to aspiration or anaerobic pneumonia: alcoholism or other causes of altered consciousness, anesthesia, dysphagia or pharyngeal dysfunction, gingivitis or pyorrhea (purulent inflammation of the gums), blunt or penetrating chest trauma or lung surgery, obstruction due to neoplasm, bronchiectasis, or pulmonary embolism. Bad breath or putrid sputum may be noted. However, the absence of a foul odor does not exclude the possibility of anaerobic infection, since certain anaerobes do not generate the end products of metabolism responsible for this type of odor, and communication may be lacking between the lesion and tracheobronchial tree. A change in sputum production, either increased or decreased, may be noted in patients with chronic bronchitis or bronchiectasis.

The patient with primary lung abscess gradually develops fever, cough, pleurisy, chest heaviness, shoulder pain, and malaise. Pneumonia may be present or suspected from history for a period of 1 to 3 weeks before the recognition of the lung abscess. By contrast, secondary lung abscesses—due, for example, to septic pulmonary emboli with infarction—can evolve over 48 to 72 h (Fig. 127-4). Clinically, the distinction between primary and secondary abscesses may be unapparent at the time of presentation but is important in the proper management of the patient. Thus, the patient with staphylococcal or streptococcal endocarditis may present with pneumonia, lung abscess, and empyema. The main clue to the presence of underlying endocarditis may be the development of new lung abscesses during the course of therapy. The patient with lung abscesses complicating subdiaphragmatic infection, for example, due to amebic abscess of the liver or pancreatic phlegmon, may have abdominal signs in addition to acute pulmonary disease. Seizures due to brain abscesses are occasionally the presenting clinical manifestation of bacteremia due to lung abscesses.

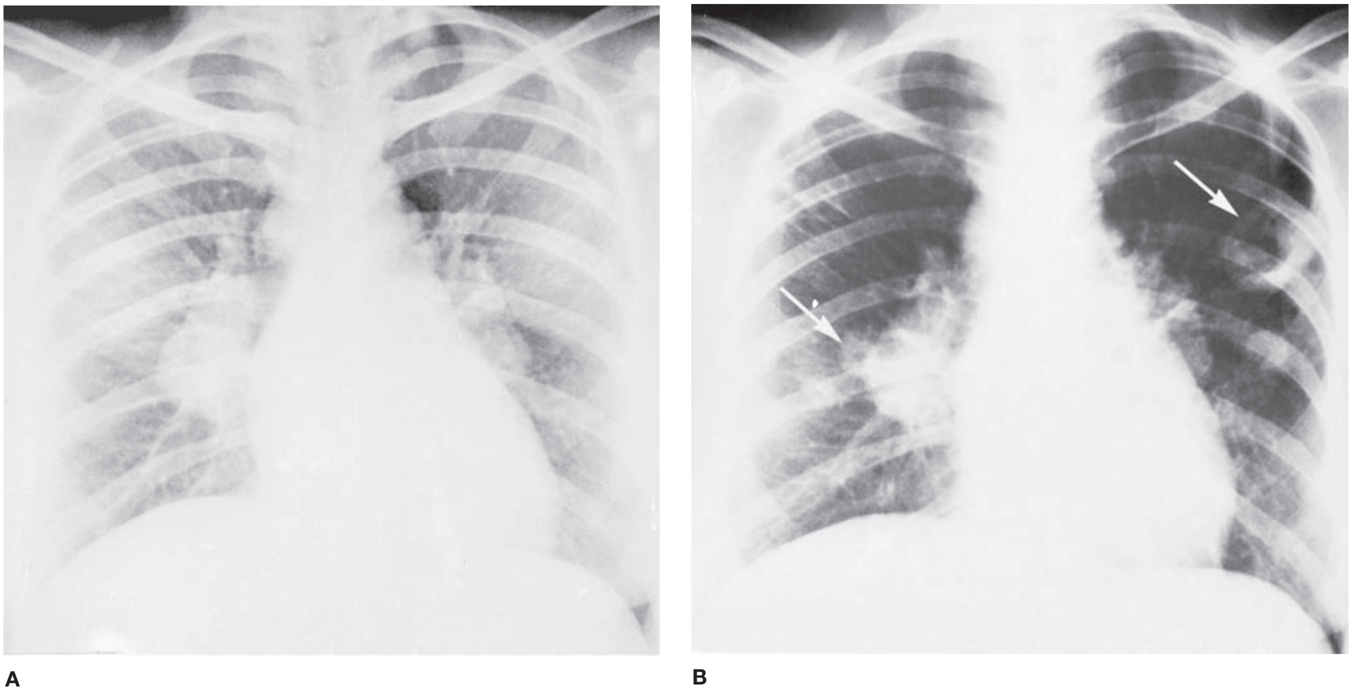

Figure 127-4 Septic emboli due to *Pseudomonas aeruginosa* in a 33-year-old woman with sarcoidosis and pyelonephritis following spontaneous abortion. The patient presented with headache, fever, backache, and purulent sputum. Pseudomonas grew from the sputum culture. **A.** Chest radiograph before present illness. Figure 127-4 *(Continued)* **C.** Lateral view. The lesions are more dramatically seen.

Radiologic Diagnosis

The classic radiographic appearance of a lung abscess is an irregularly shaped cavity with an air–fluid level. Because the presentation is often indolent, numerous chest radiographs may be needed to follow the evolution of pneumonia into necrotizing pneumonia and then a pulmonary cavity (Figs. 127-5 and 127-6). Anaerobic infection is suggested by rapid pulmonary cavitation within a dense segmental consolidation; there may be rapidly enlarging nodular lesions, with or without cavitation. Although anaerobic pulmonary infections may be acute and fulminating, almost two-thirds have a subacute or chronic presentation. The natural progression of virulent infection, delays in appropriate therapy, or tissue infarction may allow the underlying infection to progress into pulmonary gangrene (Fig. 127-6). Seeding of infection or rupture of a lung abscess into the pleural space may cause empyema (Fig. 127-4). Up to one-third of lung abscesses may be accompanied by empyema. Solitary cavities are generally observed with primary lung infections, whereas many smaller collections may be found in metastatic infection. Chest tomography will define the size and location of abscesses and may distinguish between related processes (empyema, infarction) better than conventional radiographs (Fig. 127-7). The common organisms and conditions associated with lung abscesses are listed in Table 127-6.

Laboratory Diagnosis

Microbiologic specimens from patients with lung abscesses should be obtained, if possible, without contamination by oral flora, especially after nosocomial colonization. Thus, invasive procedures are preferred to routine sputum samples. In particular, the diagnosis of anaerobic infection is complicated by the prevalence of large numbers of anaerobes as normal flora in the mouth and upper respiratory tract (Figs. 127-8 and 127-9). However, there may also be significant colonization with nosocomially acquired pathogens in hospitalized patients.

Blood and sputum cultures should be obtained as adjunctive guides to therapy. When empyema or bacteremia complicates lung abscess, adequate specimens for microbiologic evaluation may be obtained from the pleura or blood. However, to obtain adequate specimens from the abscess, bronchoalveolar lavage, the use of a protected double-lumen catheter, or percutaneous transthoracic aspiration under radiographic guidance is recommended. The specific procedure selected depends on the location of the infection and the expertise of the institution. Specimens collected through a fiberoptic bronchoscope, using bronchoalveolar lavage or a plugged double-lumen sampling catheter with a protected sampling brush, are generally preferred; these require the use of quantitative cultures. Growth at a dilution of 10 from a protected brush represents

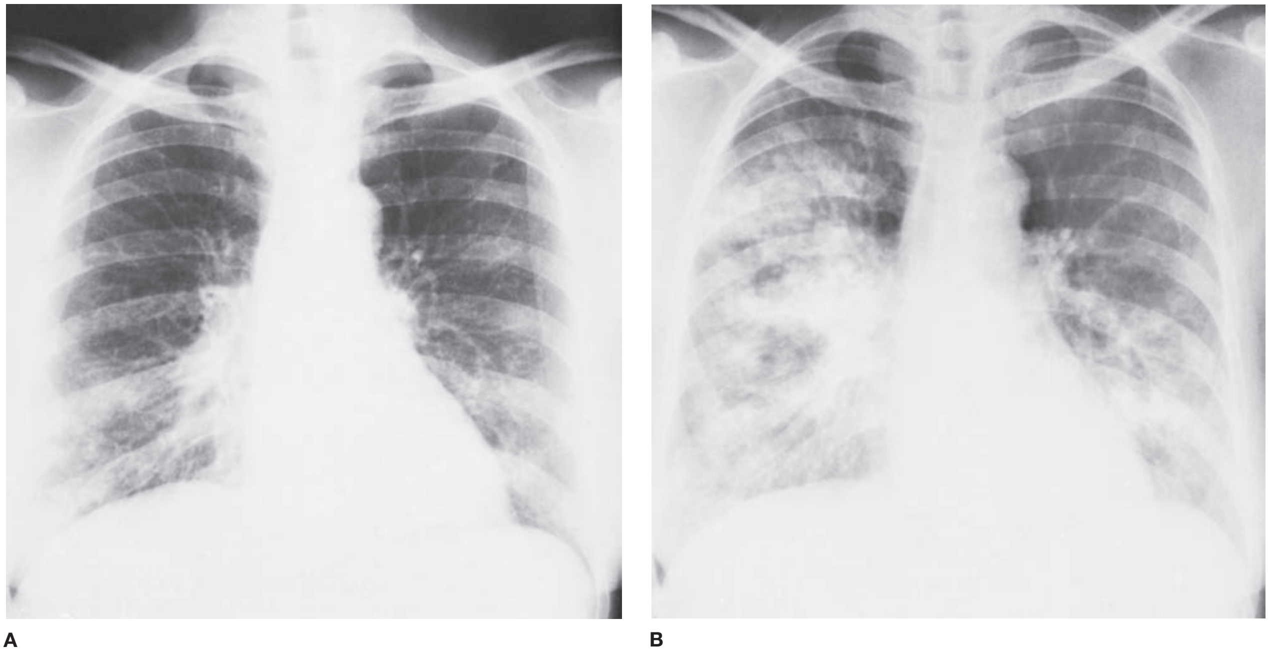

Figure 127-5 Fulminating anaerobic pneumonia in a 44-year-old woman with onset of pneumonia 6 days before admission. **A.** Day of admission. Patchy consolidation in right lower lung field and behind the cardiac silhouette. **B.** One day after admission: Extensive patchy alveolar infiltrates bilaterally with areas of rarefaction on right suggestive of cavitation. The patient died 2 days later.

approximately 10^{10} organisms per milliliter in the lower respiratory tract. Recovery of nonbacterial and anaerobic bacteria from these specimens has not been well standardized. Specimens obtained from blind, deep suctioning via an endotracheal tube may also be useful if cultured quantitatively and examined microscopically.

■ Treatment

The treatment of lung abscess must be guided by the microbiology and knowledge of any underlying or associated conditions that may predispose to the development of severe pulmonary infection. A small abscess in an otherwise healthy person may respond to conservative management with antimicrobial therapy and chest physical therapy. A rapidly expanding pulmonary abscess in an immunocompromised host (e.g., due to mucormycosis) requires urgent lung resection in addition to antimicrobials. Intermediate to these approaches is the use of bronchoscopic-guided or radiographically guided catheter drainage of any fluid and necrotic debris. In the absence of antibiotics, the mortality of lung abscess is approximately 33%.[105] However, up to half of patients surviving a lung abscess acutely in the preantibiotic era had significant pulmonary complications, including recurrent infections and abscesses, pleural empyema and adhesions, chronic bronchitis, and bronchiectasis. The introduction of penicillin, orally or parenterally administered, resulted in resolution or collapse of the abscess in up to 90% of patients (although long courses of treatment were often needed). Therefore, these patients could avoid surgical resection.

The role of drainage or surgery is based on serial clinical assessments of the patient. Bronchoscopic drainage may be most useful

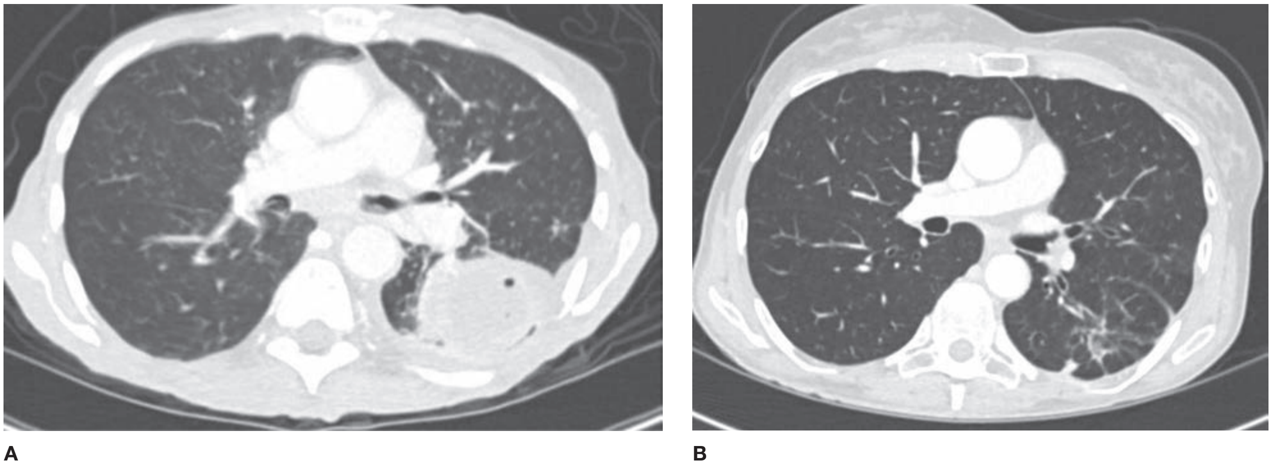

Figure 127-7 CT of a pulmonary abscess in 64-year-old with COPD (**A**) prior to antibiotics and (**B**) 2 months after antibiotics. Bronchoscopy and CT cultures were nondiagnostic.

TABLE 127-6 Organisms and Conditions Associated with the Radiographic Appearance of Lung Abscess

Infectious
Bacteria
Anaerobes, *Staphylococcus aureus*, Enterobacteriaceae (e.g., *Klebsiella pneumoniae*), *Pseudomonas aeruginosa*, *Burkholderia pseudomallei*, streptococci, *Legionella* spp., *Nocardia asteroides*, *Rhodococcus equi*, *Actinomyces* spp.
Mycobacteria (often multifocal)
M. tuberculosis, *M. avium* complex, *M. kansasii*, *M. malmoense*, other nontuberculous mycobacteria
Fungi
Aspergillus spp., zygomycetes, *Histoplasma capsulatum*, *Blastocystis hominis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Pneumocystis jiroveci*, *Penicillium marneffei*
Parasites
Entamoeba histolytica, *Paragonimus westermani*, *Strongyloides stercoralis* (postobstructive)
Miscellaneous
Empyema (with air–fluid level), septic embolism (endocarditis)
Noninfectious and Predisposing Conditions
Anatomic, fluid-filled cysts, bland infarction, bronchiectasis, vasculitis, Goodpasture syndrome, granulomatosis with polyangiitis (formerly Wegener granulomatosis), periarteritis, obstruction (neoplasm, foreign body), pulmonary sequestration, pulmonary contusion, carcinoma

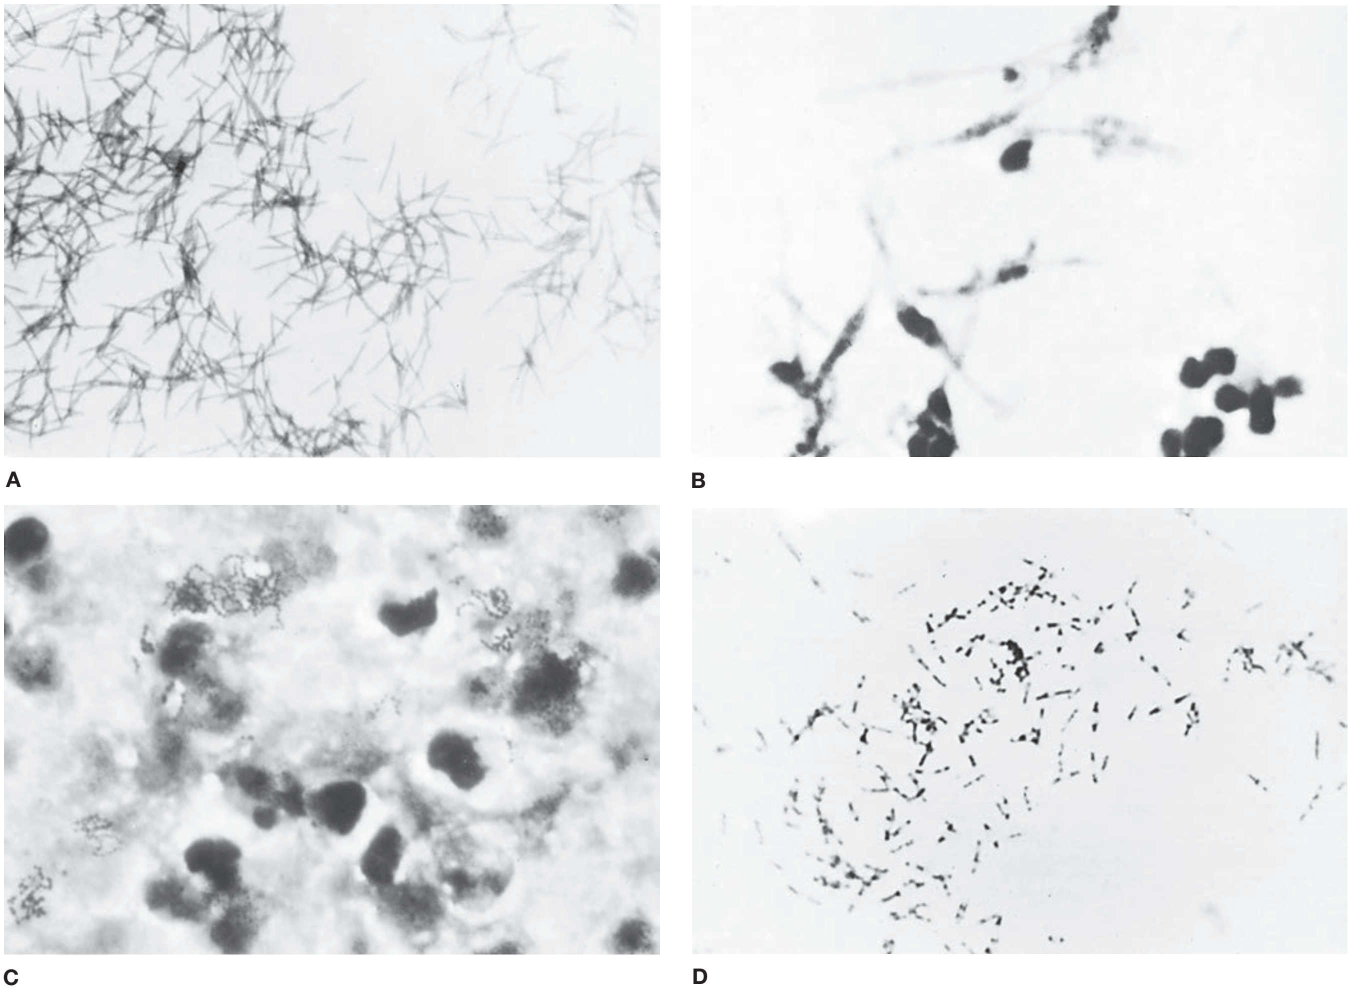

Figure 127-8 Bacteriology of empyema and lung abscess. **A.** *Fusobacterium nucleatum*, microscopic morphology. Organism is a thin and delicate Gram-negative bacillus with tapered ends (sometimes filamentous). **B.** Pleomorphic Gram-negative bacillus with filaments containing swollen portions and with large round bodies. This appearance is seen with *F. necrophorum*, *F. mortiferum*, and *F. varium*. **C.** Pus showing microaerophilic streptococcus. **D.** Microscopic morphology of *Bacteroides fragilis*. Organism is an irregularly stained, Gram-negative rod. Bipolar staining may be seen.

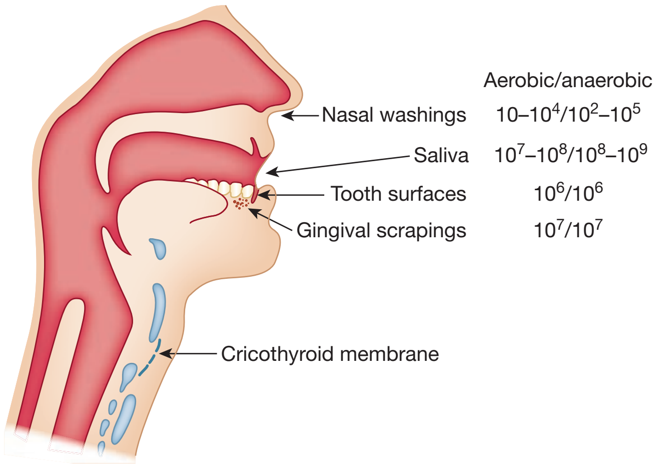

Aerobic/anaerobic

in the relief of abscesses without air–fluid levels, which indicate the possibility of a persistent connection with the bronchi.[106] However, experience dictates caution with the bronchoscopic drainage of closed cavities; spillage of cavity contents into other lung segments may produce catastrophic pulmonary dysfunction. Further, there are few data to suggest that bronchoscopic drainage offers a significant advantage in terms of rapidity of recovery in the immunologically normal host. In patients with coexistent empyema and lung abscess, it is often useful to address drainage of the empyema first, stabilizing the patient and then considering further procedures for the lung abscess. In critically ill patients or those with bronchial obstruction related to the abscess cavity, bronchoscopic drainage should be considered.

Bronchoscopy and chest CT have major roles in the evaluation of the patient failing therapy. Persistence of bacteremia or high-grade fevers after 72 h, or the absence of change in sputum production or character or in the radiographic images over 7 to 10 days, suggests unappreciated anatomic or microbiologic problems. Obstruction or resistant organisms (including fungi, parasites, or mycobacteria) may be present. Multiple loculations may be present, or empyema, including drainage of the abscess into the pleural space, may develop. New sites of infection, including extrathoracic sites, may have developed in the bacteremic patient. Progression of pulmonary infiltrates may occur after the initiation of appropriate antibiotic therapy, reflecting the relatively poor activity of many antibiotics at the low pH levels of poorly ventilated and underperfused, infected lung tissues, as well as the delayed radiographic response to treatment.

Surgical resection of necrotic segments of the lung is helpful if the response to antibiotics is poor, for large abscesses, or when ventilation–perfusion scans suggest little residual lung function in a limited necrotic region. Infarcted lung or rapidly progressive infection may force surgical resection of the affected tissue. Surgery is also indicated if airway obstruction limits drainage. Such presentations are seen in the presence of a tumor or a foreign body. In patients thought to be poor surgical risks, percutaneous drainage via catheters may be a useful temporizing measure. However, leakage of the abscess contents into the pleural space in such patients may be disastrous and must be avoided.

Mortality in patients with lung abscesses reflects the quality of the host's inflammatory response and overall condition. Patients with large abscesses (over 5–6 cm), progressive pulmonary necrosis, obstructing lesions, aerobic bacteria (especially *K. pneumoniae*, *S. aureus*, or *P. aeruginosa*), immune compromise, old age, malnutrition, or systemic debility, and those with major delays in seeking medical attention have a significantly increased mortality.[107]

EMPYEMA

The microbiology, diagnosis, clinical features, and management of empyema are considered below.

■ Microbiology

Pleural infections are associated with a significant degree of morbidity and mortality, with death or surgical intervention in more than 30% of patients.[108,109] In the preantibiotic era, up to 11% of cases of pneumococcal pneumonia were associated with empyema, and 64% of all cases of empyema were associated with *S. pneumoniae*. β-Hemolytic streptococci (15%) and staphylococci (8%) were the other organisms most commonly isolated from empyema fluid. In the 1960s and 1970s, with new culture techniques, one study found only anaerobic bacteria in pleural empyema fluid in 35% of cases, and a mixture of aerobic and anaerobic bacteria in 41% in a series of 83 medical patients who had not received antibiotics or surgical intervention (Tables 127-7 and 127-8; Figs. 127-8, 127-10,

and 127-11). With the introduction of sulfa drugs and penicillins, the expansion of thoracic surgery, and the emergence of antibiotic resistance in staphylococci, the isolation of *S. pneumoniae* from empyema fluids decreased, and that of *S. aureus* and other nosocomial pathogens increased. In more recent studies of empyema, the pneumococcus accounts for only 5% to 10% of cases, whereas anaerobes are found in 25% to 40%. The highest yield reported in recent years is a collaborative study at Cook County Hospital in Chicago and two VA hospitals in Los Angeles. Anaerobes were recovered in 63 (76%) of 83 cases.[4]

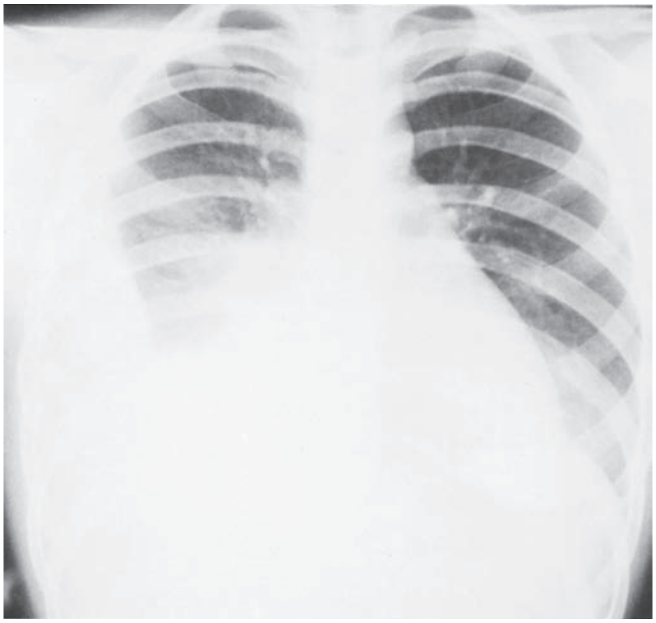

Figure 127-10 Large anaerobic empyema accompanying right middle-lobe pneumonia.

Anaerobic Bacteria in Empyema

The frequency of anaerobic infection of the lung and pleural space is a function of the colonization pattern of the individual patient, including the presence of hospital-acquired pathogens and the role of aspiration in many of these infections (Tables 127-7 and 127-8). The most frequent isolates are the anaerobes *Prevotella*, *F. nucleatum*, and *Peptostreptococcus*, and the streptococci. In early studies, the *B. fragilis* group was isolated from 15% to 20% of patients with anaerobic pleuropulmonary infections. However, later studies employing newer techniques and utilizing newer taxonomic criteria found *B. fragilis* group in only 6.8% of 46 patients with pleural empyema specimens. The *B. fragilis* group is important because of resistance to penicillin (a property shared by a number of common anaerobes) and other antimicrobial agents. Subdiaphragmatic infection may extend to the lung or pleural space by way of lymphatics, directly through the diaphragm or defects in it, or by way of the bloodstream. Anaerobic pulmonary and pleural processes rarely extend to the chest wall unless associated with actinomycosis, tuberculosis, or tumor.

Nonanaerobic Infections

In immunologically normal adults, the aerobic organisms currently most often associated with empyema and lung abscesses are *S. aureus*, β-hemolytic streptococci, and various Gram-negative aerobic or facultatively anaerobic bacilli, particularly *P. aeruginosa*, *E. coli*, *Klebsiella* species, and other nosocomial enteric Gram-negative organisms—reflecting infections associated with pneumonia treated with antimicrobial agents to which the causative organism is resistant, with thoracic surgery or high-grade bacteremias. Mixed aerobic–anaerobic infections are often related to subdiaphragmatic processes. Increasingly, *Mycobacterium tuberculosis*, *Nocardia asteroides*, and fungi have been identified. In the immunocompromised host, the infecting organisms will more often be Gram-negative bacteria (especially *Pseudomonas* and *Enterobacter)*, less virulent streptococci, *Aspergillus*, other fungi (e.g., *Mucoraceae*, *Fusarium* species, *Scedosporium* species, *Cryptococcus* species, rarely *Candida*

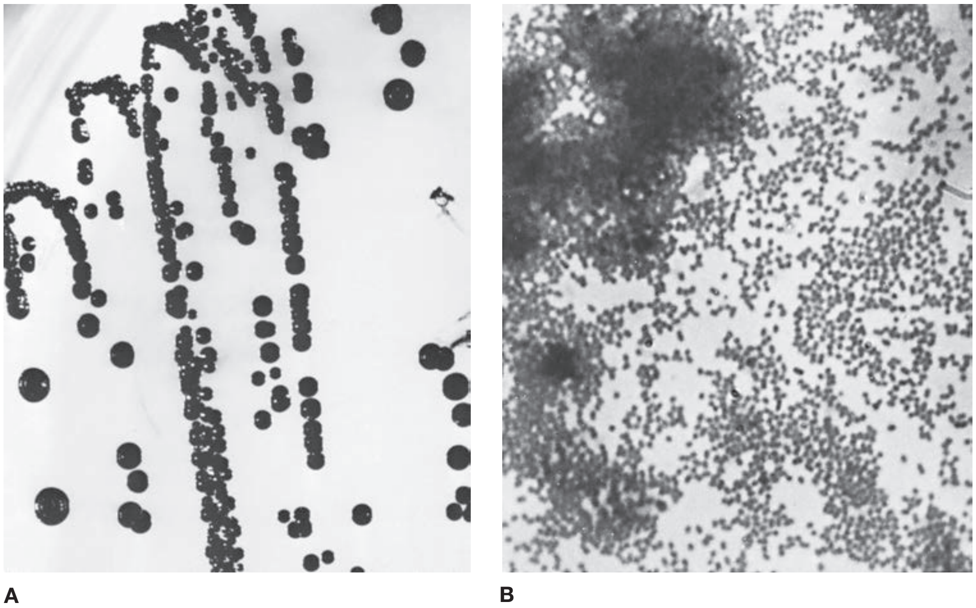

Figure 127-11 *Prevotella melaninogenica*. **A.** Distinctive black colonies (on blood-containing medium); pigment is hematin. **B.** Microscopically, the organism is a coccobacillus.

species), or will be due to reactivation of latent or subclinical infections due to *M. tuberculosis*. In all hosts, the colonization pattern of the individual will often predict the causative organisms, even if these are not easily isolated.

■ Clinical Features

The pathogenesis and presentation of both pleural empyema and lung abscesses are often indistinguishable. Shared presentations of empyema and lung abscess include the indolent development of symptoms, most often fever, sweats, cough, dyspnea, weight loss, and pleurisy; an association with conditions predisposing to aspiration events (altered consciousness, dysphagia, and gingivitis); and foul odors of sputum or breath associated with anaerobic bacteriology. Lung abscesses and empyemas often coexist. Both are generally associated with primary pneumonias.

The clinical presentation of empyema is determined by the underlying cause of infection. Empyema associated with aspiration pneumonia may develop over 1 to 3 weeks, usually with associated symptoms of pneumonia. The patient may have high fever and leukocytosis. Physical examination reveals dullness to percussion and decreased breath sounds on auscultation. These changes may be quite localized in the setting of loculated fluid. The empyema fluid is generally purulent by the time of detection, but pleural infection may be noted only after treatment for pneumonitis has failed to resolve fever or pleurisy. Empyema associated with thoracic surgery may be radiologically “hidden” in areas of the chest not drained by chest tubes or behind relatively benign pleural effusions. The patient may appear minimally toxic or severely ill, depending on the extent of the infection and organisms present. The presentation is modified by routine prophylactic antibiotic use, sedation, intubation, and antipyretics. Acute empyema may be seen in staphylococcal and streptococcal infections and following rupture of hepatic abscesses, especially those due to *E. histolytica*.

■ Radiologic Diagnosis

With empyema, chest radiographs generally reveal fluid, most often in the costophrenic angles; free-flowing effusions layer on lateral decubitus radiographs. The use of bedside ultrasound (Fig. 127-12) is useful in guiding drainage of these fluid pockets. Loculations and pleural disease are often best defined by computed tomography of the chest, which should include the neck and diaphragms to rule out extrathoracic sites of infection. Spinal disease is better detected with magnetic resonance imaging (MRI). Before invasive diagnostic procedures, a careful history and physical examination may suggest a reason for the accumulation of pleural fluid. Noninfectious causes include bland pulmonary embolus, malignant effusion, benign postsurgical changes, pericardiotomy syndrome, collagen vascular diseases (systemic lupus, rheumatoid arthritis), congestive heart disease, sympathetic effusion related to subdiaphragmatic disease (pancreatitis), leakage of ascites or peritoneal dialysis fluids, and hemorrhage (from venous access catheters or aortic tears).

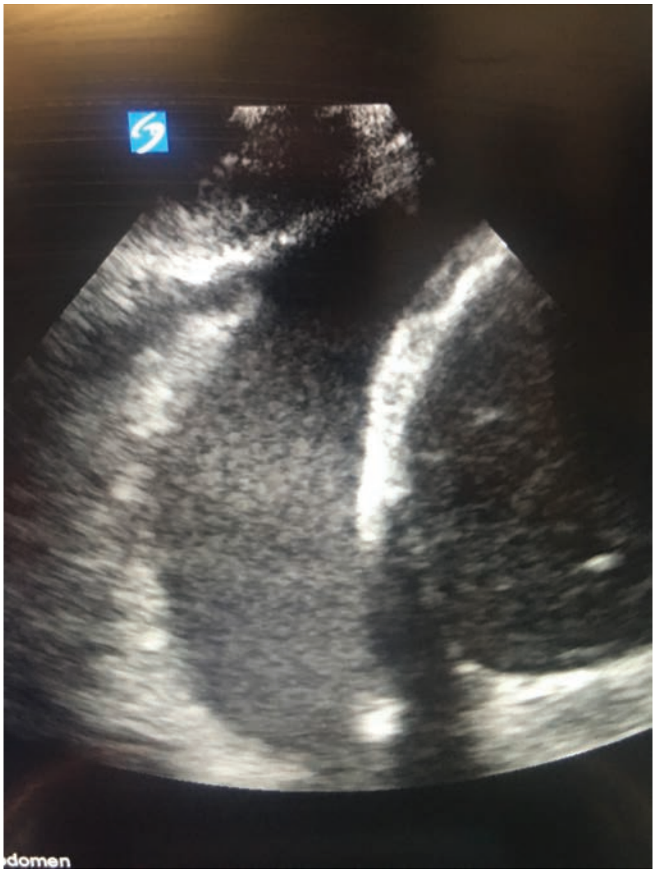

Figure 127-12 Ultrasound of pleural fluid pocket.

Infectious causes include extension of all classes of pulmonary infections from the lungs (parapneumonic), esophageal rupture, parapharyngeal space drainage, drainage, or sympathetic effusion due to hepatic or subdiaphragmatic abscesses, septic metastasis, and direct infection via thoracic defects or chest tubes used for pleural drainage. Pyopneumothorax, in the absence of bronchopleural fistula, prior surgery, or prior thoracentesis, suggests the possibility of gas formation by bacteria implicated in the infection. Although nonspecific, pyopneumothorax suggests a component of anaerobic infection.

Laboratory Diagnosis

The diagnosis of empyema is based on the characteristics of thoracic fluid. The urgency for diagnosis is due to the development of pleural scar and of loculated effusions in the presence of undrained pus. Thus, diagnostic thoracentesis should be attempted unless the nature of the pleural fluid is clear or the clinical risk to the patient is too great. Pleural fluid analysis should include Gram stain and cultures (routine, anaerobic, mycobacterial, and fungal), parasitologic examination when appropriate, fluid cell count and differential, cytology, pH, lactic dehydrogenase, total protein, and glucose measurements at a minimum (Chapter 76). Purulent fluid requires drainage. Empyema is diagnosed on the basis of the neutrophilic predominance in fluids with more than 25,000 white blood cells per milliliter. Parapneumonic effusions will generally have lower white blood counts, negative Gram stains and cultures, a pH over 7.3, and glucose greater than 50% of serum glucose levels. Parapneumonic fluids may become infected over time. Blood cultures and sputum cultures should be obtained as adjunctive guides to therapy.

Treatment

The management of empyema includes antimicrobial treatment, identification and treatment of any anatomic processes, and drainage of the infected fluid. The approach to a specific patient is based on the clinical status of the patient as well as the microbiology of the infection. For example, patients with empyema following thoracic surgery and other hospitalized patients may have useful culture data available from chest tube drainage samples or sputum cultures to assist in the selection of antibiotics. The Gram stain may indicate the predominant organism type. Mixed aerobic and anaerobic organisms may be the first suggestion of esophageal tear or parapharyngeal infection. Fastidious organisms (*S. pneumoniae*, anaerobes) may be seen on Gram stain but not isolated in culture. Antibiotic susceptibility data should be used to guide therapy, especially in nosocomially acquired infection. Local administration of antibiotics (e.g., inhaled, instilled) is unnecessary and may be irritating; intrapleural injection of antibiotics should be reserved for pleural ablation (pleurodesis), as may be achieved with erythromycin.

The decision to drain a pleural fluid collection is based on the characteristics of the fluid. In the presence of pleural fluid and unexplained fever, leukocytosis, or bacteremia, or in the postoperative patient, thoracentesis should be performed routinely. Noninfected parapneumonic pleural effusions resolve with appropriate treatment

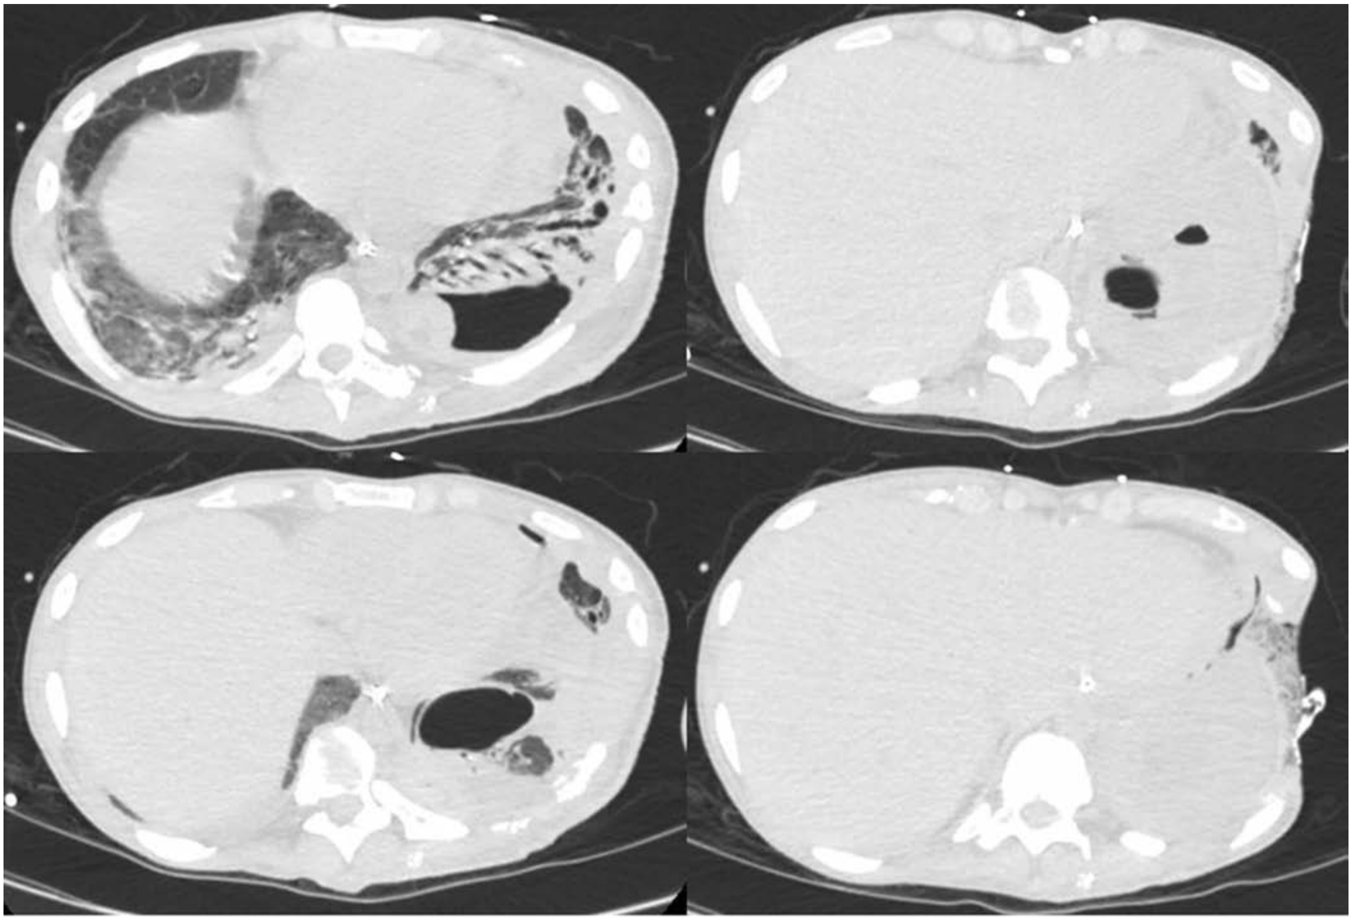

Figure 127-13 Representative cross-sectional imaging of an 18-year-old male, previously described in Fig. 127-2. The patient underwent decortication and construction of an Eloesser flap, shown here, for a right-sided empyema that led to trapped lung. At the time these images were obtained, a wound vac was in place at the flap site. Ongoing trapped lung ultimately required a second decortication procedure.

of the underlying infections. Drainage is required if infection or frank pus is present. Highly viscous or purulent fluids and fluids with acid pH also require the insertion of a chest tube via thoracostomy or the thoracoscopic drainage of the fluid. In approximately one-third of patients, however, drainage through a chest tube along with antibiotic treatment fails to cure an empyema, necessitating surgical intervention.[110] This may be improved through use of DNase plus tissue plasminogen activator (t-PA) instilled through the chest tube. The use of these two agents in combination has been shown to decrease the number of patients who require surgical intervention.[111]

In the early or exudative phase of parapneumonic effusion, the fluid is thin and serous or serosanguineous. This may resolve during appropriate antibiotic therapy either without drainage or with multiple needle aspirations. If the pH is over 7.3, this method may be preferred. If the pH is less than 7.0, however, complete drainage should be performed, often requiring closed chest tube insertion. If the pH is between 7.0 and 7.3, failure to demonstrate improvement of infection or inflammation on multiple thoracenteses over 3 to 4 days should lead to consideration of formal drainage, especially if the primary process is adequately treated. Loculation of pleural fluid or failure to respond to antimicrobial therapy may require either multiple thoracenteses guided by ultrasound or chest tomographic evaluation (CT scans) or surgical intervention. Bloody fluid or persistent parapneumonic fluid should prompt cytologic evaluation and CT scans for lung masses or undrained mediastinal or retrocardiac collections.

Empyema diagnosed later in the course, persistently infected pleural fluid, viscous fluid, or fluids with acid pH may require large-bore tube drainage. This heavily proteinaceous fluid is characteristic of the fibropurulent phase of the evolving empyema. Indications for closed chest tube placement include bronchopleural fistula with empyema, loculated fluid unresponsive to thoracentesis and antibiotics, the presence of blood clots, and rapidly accumulating empyema not otherwise manageable. Under suction, and with removal of the gel-like material, pus, and clots, the lung expands and obliterates the empyema space. Failure to expand the underlying lung, persistence of drainage beyond 7 days, inability to achieve drainage assessed radiologically, fever without change in 2 to 3 days, or pus formation with persistent infection (as opposed to colonization of the chest tubes) necessitates a search for undrained foci of infection, failure to close a bronchopleural fistula or esophageal tear, undetected rupture of a lung abscess, or antibiotic failure. As the infection enters the chronic phase, open drainage with rib resection or pleurocutaneous fistula formation (such as with an Eloesser flap, Fig. 127-13) may be needed, with or without decortication, to achieve lung expansion and healing. Open drainage is obtained by making the pleura adherent to the chest wall during the insertion of chest tubes directly into the empyema cavities. Drainage achieved too late in the course of infection may result in the development of pleural scar and fibrous peel with restrictive pulmonary physiology. Decortication may be needed to achieve sterilization of the pleural space and restore lung expansion. Thoracoscopic drainage of empyema has been used with excellent results at a number of institutions, particularly in children. Often, thoracoscopic drainage of empyema is used as a temporizing maneuver (e.g., following acute rupture of a lung abscess into the pleural space). Patients achieving rapid re-expansion of the lungs may avoid open drainage procedures while achieving limited decortication and disruption of loculations. Alternatively, once a patient is stabilized and can better tolerate open drainage or has demonstrated an inability to resolve the empyema without further drainage, surgical intervention may be needed. Early, aggressive treatment of empyema may reduce the duration of hospitalization and the risk of nosocomial superinfection.

CHAPTER 128

Acute Bronchitis and Community-Acquired Pneumonia

James M. Walter
Richard G. Wunderink

INTRODUCTION

Acute bronchitis (or tracheobronchitis) and community-acquired pneumonia are two prevalent disorders in the general population. In this chapter we discuss important clinical aspects of these infections, including diagnostic approaches and treatment strategies.

ACUTE BRONCHITIS

Acute bronchitis is inflammation of the large airways without evidence of pneumonia. Approximately 5% of adults develop acute bronchitis in a given year, resulting in approximately 100 million ambulatory care visits in the United States.[1] Consumers in the United States spend roughly $7 billion annually on the management of cough—the most common symptom of acute bronchitis.[2]

Respiratory viruses, including rhinovirus, coronavirus, parainfluenza virus, respiratory syncytial virus, human metapneumovirus, and influenza virus, are responsible for up to 90% of cases (although many patients with acute bronchitis do not have a specific pathogen identified).[1,3] The important role of respiratory viruses in disease pathogenesis helps explain the increased incidence of acute bronchitis in the fall and winter. *Bordetella pertussis*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* are the bacteria most frequently identified in immunocompetent adults with acute uncomplicated bronchitis in the absence of chronic lung disease.[4] *Moraxella catarrhalis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae* are more common in patients with chronic obstructive pulmonary disease (COPD) and possibly in smokers without overt COPD.

Cough, with or without sputum production, is the hallmark of acute bronchitis. Although patients with purulent sputum are more frequently prescribed antibiotic therapy, sputum appearance is an unreliable surrogate for bacterial infection and does not identify patients more likely to benefit from antibiotics.[4,5] On average, cough lasts for 10 to 20 days but can persist for more than a month.[6] Patients may also endorse headaches, rhinorrhea, and mild constitutional symptoms.

Given the self-limited nature of acute bronchitis, the goal of a clinical evaluation is to exclude potentially life-threatening diagnoses whose symptoms may overlap with acute bronchitis, including pneumonia and exacerbations of asthma, COPD, and congestive heart failure (CHF). In younger patients without comorbidities, a persistent cough coupled with normal vital signs and a reassuring physical examination is sufficient to diagnose acute bronchitis.[7] For elderly patients and those with chronic health conditions, basic laboratory testing and a chest radiograph are often required to exclude more concerning diagnoses.

Although a large number of both over-the-counter and prescription pharmacotherapies are available for the symptomatic management of acute bronchitis, evidence to support the efficacy of any specific medication is minimal.[8,9] Guidelines do not recommend the routine prescription of antitussives, inhaled bronchodilators, oral corticosteroids, or other oral anti-inflammatory medications.[7] Management is, therefore, supportive, and plans should be made for clinical re-evaluation if a patient experiences persistent or progressive symptoms. The development of "red flag" symptoms including hemoptysis, worsening dyspnea, weight loss, difficulty swallowing, and persistent fever should trigger a more urgent evaluation.[10]

An ongoing challenge in the management of acute bronchitis is the recalcitrant nature of antibiotic overuse. Guidelines from professional societies and the Centers for Disease Control and Prevention (CDC) uniformly recommend avoiding antibiotics for acute uncomplicated bronchitis.[1,11] Indeed, the Infectious Diseases Society of America (IDSA) includes a recommendation to avoid antibiotics for acute bronchitis as one of their five statements for the Choosing Wisely campaign.[12]

Despite these recommendations and consistent evidence that antibiotics provide minimal benefit for patients with acute bronchitis, many patients continue to receive antibiotics.[13,14] In an analysis of ambulatory care prescription practices in the United States from 1996 to 2010, the overall antibiotic prescription rate for acute bronchitis was 71%, a rate that actually rose during the study period.[15] Similarly, in a 2020 evaluation of data from a large U.S. healthcare network, 21% of patients evaluated in the outpatient setting for respiratory conditions for which antibiotics were not indicated (including acute bronchitis) received antibiotic therapy.[16]

Reducing antibiotic use for acute bronchitis is the focus of ongoing efforts by professional societies and the CDC.[1,17] Results from a Cochrane group review suggest C-reactive protein (CRP) testing, procalcitonin-guided management, and shared decision-making may be valuable tools to aid these efforts.[18]

COMMUNITY-ACQUIRED PNEUMONIA

Pneumonia is defined as an infection of the pulmonary parenchyma from the level of the respiratory bronchioles to alveoli.[19] Clinically, pneumonia can be recognized by the presence of a new lung infiltrate coupled with any of the following: new or increased cough, dyspnea, pleuritic chest pain, purulent sputum, confusion, fever, hypoxemia, rales, leukocytosis, or leukopenia.[20]

Introduction

The diagnosis and treatment of pneumonia is guided by the setting in which it develops. Pneumonia that occurs in community-dwelling individuals is termed *community-acquired pneumonia* (CAP). *Hospital-acquired pneumonia* (HAP) is defined as pneumonia that occurs 48 h or more after hospital admission, while *ventilator-associated-pneumonia* (VAP) is defined as pneumonia occurring 48 h or more after endotracheal intubation.[21] *Healthcare-associated pneumonia* (HCAP), a categorization meant to identify community-dwelling individuals at particularly high risk of infection with drug-resistant pathogens, was removed from recent Infectious Diseases Society of America–American Thoracic Society (IDSA–ATS) clinical practice guidelines.

In this chapter we review the epidemiology, diagnosis, and treatment of adults with CAP. Pneumonia in severely immunosuppressed patients—including those with advanced human immunodeficiency virus (HIV) infection or prolonged neutropenia, solid organ transplant recipients, and patients undergoing chemotherapy—are not discussed here given the unique epidemiology and management considerations; see Chapter 123 for discussion of pneumonia in the immunocompromised host.[22]

Epidemiology

CAP imposes a sizeable burden on our healthcare system. While conditions such as myocardial infarction and stroke receive significantly more preventative resources, CAP is associated with higher rates of hospitalization and total healthcare costs.[23] In the United States, pneumonia accounts for 1.5 million annual visits to the emergency department (ED) and is a leading cause of admission to the hospital.[24,25] Due in part to an aging population, the number of patients with CAP who require care in the intensive care unit (ICU) has significantly increased, especially among the elderly and patients with comorbidities.[26]

CAP is the eighth leading cause of death in the United States.[27] Worldwide, lower respiratory tract infections including CAP are the fourth leading cause of mortality, accounting for 2.6 million annual deaths.[28] In low-income countries, lower respiratory tract infection trails only neonatal conditions as the leading cause of death.

In 2019, pneumonia caused 43,881 deaths in the United States with an age-adjusted death rate of 10.8 deaths per 100,000 persons.[29] Encouragingly, between 1999 and 2019, both the percentage of total deaths due to pneumonia and pneumonia mortality rates per 100,000 persons fell. However, the pace of this decline lags behind other infectious diseases such as HIV.[30] Additionally, deaths from sepsis, acute respiratory distress syndrome caused by CAP, or those in which pneumonia occurs as a complication of a chronic progressive illness, such as Alzheimer dementia or end-stage malignancy, are likely not captured in the above figures, given differences in coding intended to maximize reimbursement. Prospective incidence studies suggest a higher incidence of CAP-associated mortality than is noted in death certificates.[31,32]

While CAP is an acute time-limited illness, it is associated with increased long-term mortality. Nearly one-third of patients hospitalized for CAP die within 1 year.[32] For patients admitted to the ICU, 1-year mortality approaches 50%.[31] Patients hospitalized for CAP experience long-term mortality rates more than three times higher than matched population controls.[33] Interestingly, an episode of CAP has been shown to increase a patient's risk of long-term mortality irrespective of age.[34]

Several factors may explain these observations. CAP disproportionally impacts the elderly and those with chronic health conditions, groups at increased risk of death irrespective of pneumonia (Fig. 128-1). Multiple studies suggest that CAP increases the risk of both short- and long-term cardiovascular disease including myocardial infarction, cerebrovascular accidents, and heart failure.[35] Notably, even for patients without chronic health conditions at the time of hospitalization, post-CAP mortality is frequently driven by cardiovascular disease, cancer, or renal failure.[36] Evidence of subclinical inflammation at hospital discharge is common and is independently associated with death in the months that follow. These observations raise the possibility that CAP, or the subclinical inflammation that often follows, may accelerate the emergence of life-limiting medical conditions. This pattern is even more evident for CAP caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).

The most rigorous recent investigation of CAP epidemiology in the United States is the University of Louisville Pneumonia Study—a 2-year population-based cohort study of adults hospitalized with CAP in Louisville, Kentucky.[32] In this study, the annual age-adjusted CAP incidence was 649 patients hospitalized per 100,000 adults. Older adults experienced significantly higher rates of CAP requiring hospitalization (2093 per 100,000 persons for adults ≥65 years of age compared with 327 per 100,000 persons for adults <65 years of age). CHF and COPD were associated with the highest risk of CAP, with rates for patients with COPD exceeding 5800 patients hospitalized per 100,000 persons.

Patients with CAP frequently require care in the ICU. In a secondary analysis of the University of Louisville Pneumonia Study, 23% of patients were admitted to the ICU.[31] The incidence of CAP requiring ICU admission was 145 cases per 100,000 adults. Not surprisingly, patients older than 75 years of age and those with CHF or COPD experienced the highest incidence of ICU admission. These findings align with data from the CDC's Etiology of Pneumonia in the Community (EPIC) study in which 21% of patients required admission to the ICU.[37]

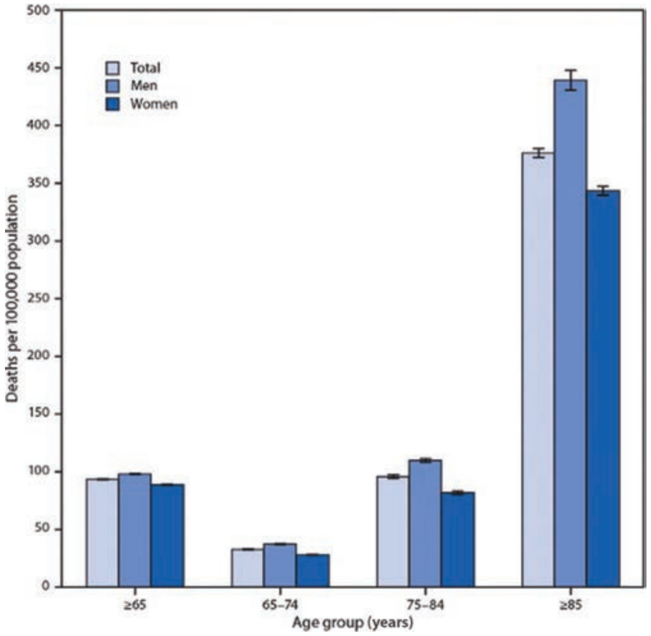

Figure 128-1 Death rates from influenza and pneumonia among persons 65 years of age or older grouped by sex and age—National Vital Statistics System, United States, 2018. *Bars* show death rates per 100,000 population within each age group; 95% confidence intervals are shown with *error bars*. *(Reproduced with permission from QuickStats: Death Rates from Influenza and Pneumonia Among Persons Aged ≥65 Years, by Sex and Age Group—National Vital Statistics System, United States, 2018. MMWR Morb Mortal Wkly Rep. 2020;69(40):1470.)*

Recognition of the important link between structural determinants of health (including but not limited to air quality, housing and food insecurity, and reduced access to healthcare services) and CAP epidemiology has been increasingly recognized.[38] When areas of Louisville were grouped according to a deprivation index, adults living in high-deprivation areas had both a higher CAP incidence and a significantly higher odds of severe CAP than adults in low-deprivation areas. These findings emphasize the need to consider socioeconomic and environmental factors when designing interventions to improve CAP prevention and treatment. The inequities observed during the coronavirus disease 2019 (COVID-19) pandemic highlight the urgency of this work.[39]

■ Microbiology

Several factors complicate an accurate characterization of CAP microbiology. Many patients who are initially diagnosed with CAP ultimately receive an alternative diagnosis. In a prospective study of 259 patients diagnosed with CAP at a Veterans Health Administration hospital, 44 (17%) were eventually diagnosed with a noninfectious cause for their symptoms including pulmonary edema, interstitial lung disease, and malignancy.[40]

Additionally, despite advances in diagnostic testing, a causative pathogen is identified for only a minority of patients with CAP. In the landmark CDC EPIC study, which performed rigorous microbiologic testing in 2259 adults hospitalized with CAP, no pathogen was identified in 62% of patients (Fig. 128-2).[37] Over the past two decades, the percentage of patients hospitalized in the United States with pneumonia who had no reported pathogen increased

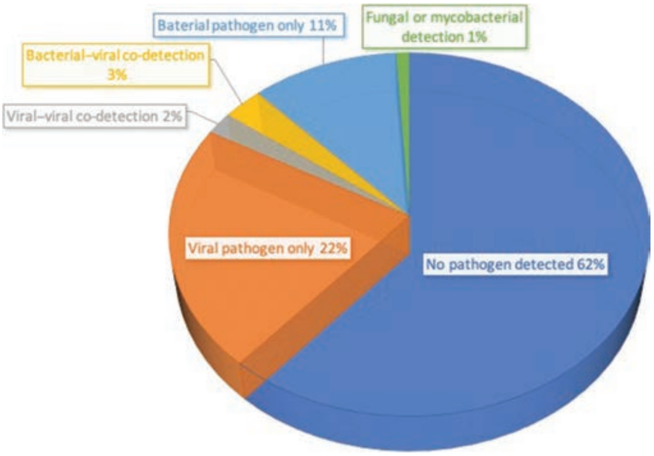

Figure 128-2 Type of pathogen detected among 2259 adults hospitalized adults with community-acquired pneumonia in the CDC-EPIC study.

by almost 20% (Fig. 128-3).[41] Factors that may contribute to the large percentage of CAP patients in whom no pathogen is identified include the widespread emphasis on prompt antibiotic administration for acutely ill patients, successful vaccination programs against *S. pneumoniae*, the variable ability of patients to provide a high-quality sputum sample, persistent limitations in our ability to distinguish "normal respiratory flora" from causative CAP pathogens, and the imperfect sensitivity of diagnostic testing of the upper airway.

Despite these diagnostic uncertainties, a clear paradigm shift in our understanding of CAP microbiology has emerged. Historically, CAP has been viewed as a bacterial disease. In the preantibiotic era, rates of *S. pneumoniae* exceeded 90%.[42] As recently as the 1990s, clinical reviews referenced *S. pneumoniae* as the etiology for between 20% and 75% of CAP.[43] Other bacteria commonly cited as "classic" CAP pathogens include *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Staphylococcus aureus*, *Moraxella catarrhalis*, and *Chlamydia pneumoniae*. Apart from influenza, common respiratory viruses were viewed as minor contributors to CAP pathogenesis in adults.

That respiratory viruses are an important, if not the predominant, cause of CAP is now clear. What accounts for this change? First, the incidence of invasive pneumococcal pneumonia has decreased due to widespread vaccination, increased awareness of the importance of early antimicrobial therapy, and decreased rates of cigarette smoking.[44] As an example, from 1998 to 2003, adults older than 50 years of age experienced nearly a 50% decline in invasive pneumococcal disease.[45] In the CDC EPIC study, only 5% of patients had documented *S. pneumoniae* infection (Fig. 128-4).[37]

Second, an aging population has resulted in an ever-increasing number of individuals particularly susceptible to severe viral infection. There are roughly 50 million adults older than 65 years of age in the United States; this number is projected to increase to more than 80 million by 2040.[46] The elderly are up to 10 times more likely to develop viral pneumonia than younger adults and experience substantially higher morbidity and mortality with viral pneumonia.[37,47,48]

Finally, ability to detect respiratory viral pathogens in clinical practice has markedly improved. Slow and labor-intensive culture-based techniques have been largely replaced by increasingly sensitive diagnostic systems that pair nucleic acid amplification with multiplex technology, allowing multiple viruses to be tested on a single sample. A single patient sample can now be simultaneously tested for up to 35 pathogens including multiple respiratory viruses, with results typically available in less than 6 h.[49]

Driven by the above trends, viral CAP is now frequently identified in clinical practice. In the CDC EPIC study, 23% of patients had a virus identified on testing, compared with just 11% with evidence of a bacterial infection.[37] Rhinovirus was the most frequently identified pathogen overall, found in 9% of patients. Similarly, in a 2016 systematic review of 31 studies, 25% of CAP patients had a viral infection detected using polymerase chain reaction (PCR)-based testing.[50] When lower respiratory tract samples are available, the prevalence of viral infection approaches 50%.[50]

Antibiotic-resistant Pathogens

An important consideration in the evaluation of patients with CAP is the accurate identification of those at risk for infection with drug-resistant pathogens including methicillin-resistant *S. aureus* (MRSA), antibiotic-resistant and multidrug-resistant (MDR) *Pseudomonas aeruginosa*, extended-spectrum β-lactamase (ESBL)-producing Enterobacterales, and *Acinetobacter baumannii* (Table 128-1).

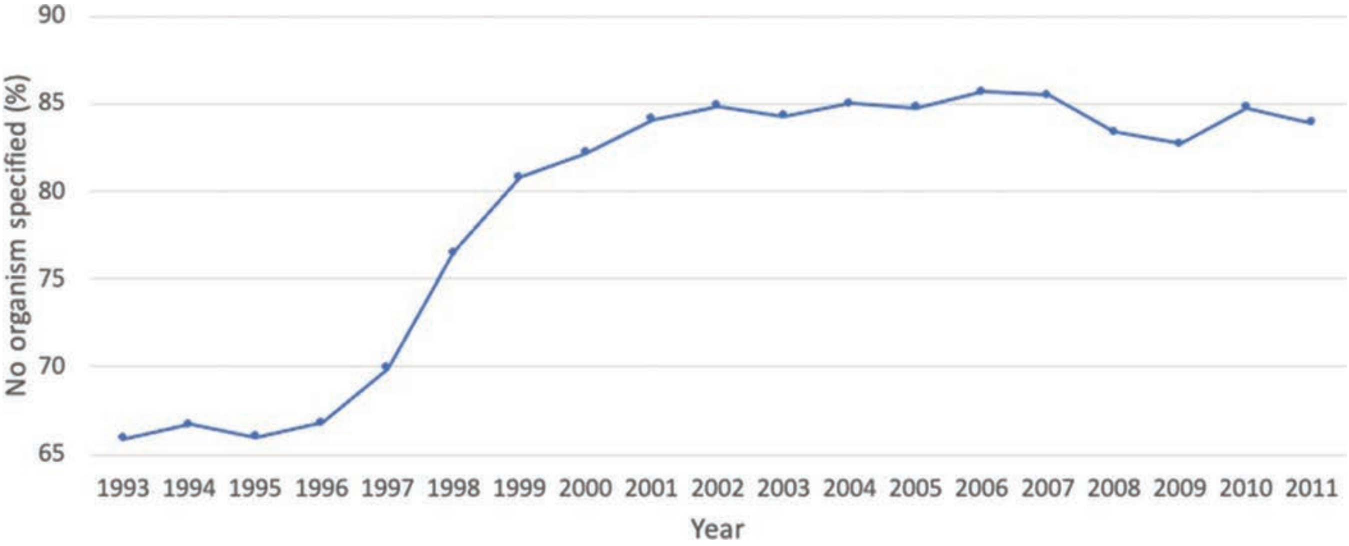

Figure 128-3 Percentage of hospital admissions for pneumonia with no pathogen identified from 1993 to 2011. *(Data from Smith SB, Ruhnke GW, Weiss CH, et al. Trends in pathogens among patients hospitalized for pneumonia from 1993 to 2011. JAMA Intern Med. 2014;174(11):1837–1839.)*

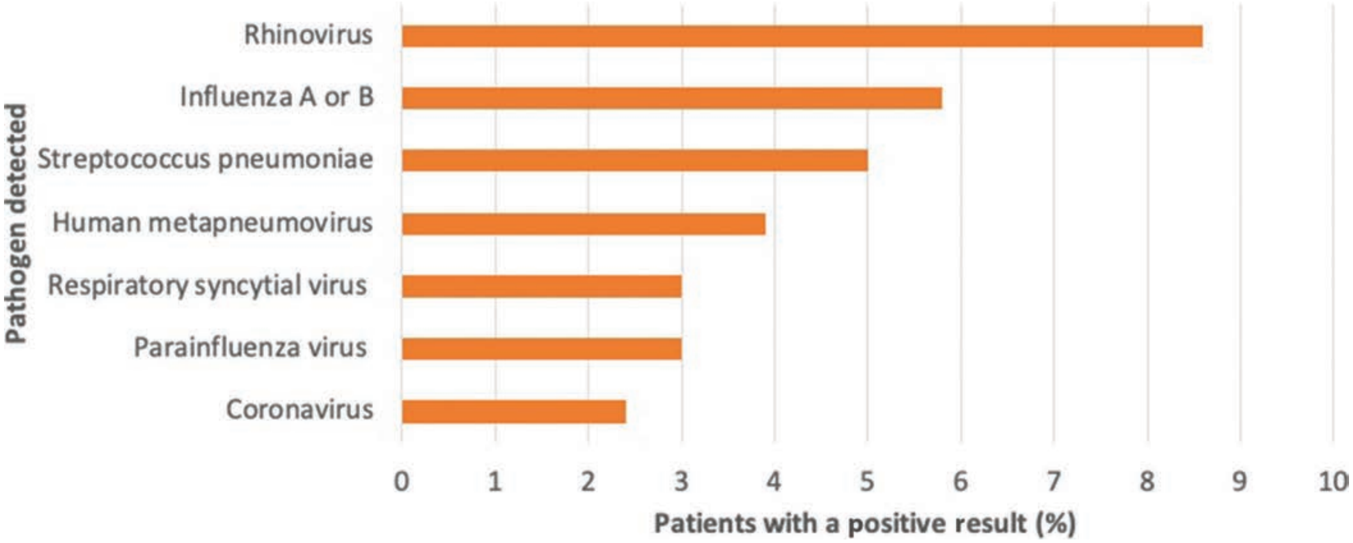

Figure 128-4 Pathogen detection among 2259 adults hospitalized adults with community-acquired pneumonia in the CDC-EPIC study. *(Data from Jain S, Self WH, Wunderink RG, et al. Community-Acquired Pneumonia Requiring Hospitalization among U.S. Adults. N Engl J Med. 2015;373(5):415–427.)*

In the Global Initiative for MRSA Pneumonia (GLIMP) study, an international multicenter point-prevalence study of 3193 patients admitted with CAP who underwent microbiologic testing within 24 h of admission, 95 (3%) were diagnosed with MRSA.[51] Among 443 patients enrolled in the United States, 22 (5%) were found to have MRSA. Risk factors independently associated with MRSA pneumonia included previous MRSA infection or colonization, recurrent skin infections, and severe disease.

In a separate analysis of the GLIMP cohort, 4.2% of patients were found to have *P. aeruginosa* while 1% were diagnosed with MDR *P. aeruginosa*.[52] In North America, 2.5% of patients were diagnosed with antibiotic-resistant *P. aeruginosa,* while 1.2% were found to have MDR *P. aeruginosa.* Independent risk factors for *P. aeruginosa* infection included prior infection or colonization with *P. aeruginosa*, tracheostomy, bronchiectasis, need for invasive respiratory support or vasopressors, and very severe COPD.

Enterobacterales were identified in 6% of the GLIMP cohort.[53] More than half these patients had an isolate resistant to at least one antibiotic, while 1.2% of the study cohort was found to have an MDR pathogen. Independent risk factors for Enterobacterales infection were male sex, severe disease, low body mass index, and prior infection with an ESBL-producing pathogen.

Although drug-resistant pathogens are an uncommon cause of CAP, early identification and timely antibiotic therapy are essential given the high mortality associated with these infections.[54] The HCAP framework was intended to aid the identification of patients most likely to benefit from empiric broad-spectrum antibiotic therapy.[55] However, the criteria's poor specificity fueled widespread antibiotic overtreatment and likely worsened outcomes.[56,57]

A number of investigators have developed prediction scores to identify patients at high risk of CAP due to drug-resistant pathogens. As an example, in a review of more than 1000 patients hospitalized with pneumonia in Japan, the strongest risk factors for infection with drug-resistant pathogens were prior hospitalization, immunosuppression, previous antibiotic use, use of gastric acid–suppressing agents, tube feeding, and nonambulatory status.[58] When 3 or more risk factors were present, the rate of infection with a drug-resistant pathogen exceeded 40%. Unfortunately, most available prediction models lack the test characteristics necessary to reliably guide antibiotic selection in high-risk patients.[59]

TABLE 128-1 Select Risk Factors for Infection with Antibiotic-resistant Pathogens in Community-acquired Pneumonia[a]

MRSA	• Prior MRSA infection or colonization • Recurrent skin infections • Severe CAP
Pseudomonas aeruginosa	• Prior infection or colonization with *P. aeruginosa* • Tracheostomy • Bronchiectasis • Need for invasive mechanical ventilation or vasopressors • Very severe COPD
Enterobacterales	• Male gender • Severe disease • Low body mass index • Prior infection with an ESBL-producing pathogen

■ Lung Microbiome

Pneumonia has traditionally been viewed as the result of a pathogenic species invading the sterile lower respiratory tract through either aspiration or inhalation. However, a growing body of literature suggests that the respiratory system in health is home to a complex microbial ecosystem that extends from the nares to the alveoli and may include microbes traditionally viewed as pathogenic.[60] Through this lens, pneumonia can be conceptualized as an abrupt breakdown in the homeostasis of the lung microbiome—a disruption that does not necessarily require the introduction of a new pathogen. This novel framework challenges the validity of discounting certain bacteria identified on respiratory culture as "normal flora." Indeed, interest in the role of pathogen-agnostic diagnostic platforms such as metagenomic sequencing to facilitate a more nuanced approach to pneumonia pathogen detection is growing.[61,62] For additional information, please refer to Chapter 121 on the lung microbiome.

■ Clinical Evaluation

The diagnostic hallmarks of pneumonia are a new infiltrate on chest imaging, clinical evidence of infection (e.g., fever or leukocytosis), and findings suggestive of respiratory tract involvement (e.g., cough, sputum production, dyspnea, or abnormalities on the pulmonary physical exam).[20]

While a detailed history and physical examination should be performed in every patient, neither is sufficient in isolation to reliably confirm or exclude CAP. In a systematic review of four studies, no findings on patient history had sufficient negative predictive value to obviate the need for additional testing.[63] Only fever, immunosuppression, and a history of dementia had positive likelihood ratios for pneumonia greater than two. Atypical features on presentation including confusion or the absence of hypoxemia are associated with significant delays in antibiotic administration.[64]

Conversely, historic features may suggest infection with a specific pathogen. For example, the presence of hemoptysis, erythematous rash, skin pustules, severe pneumonia during the summer months, and cavitary disease should raise concern for community-acquired MRSA.[65] Similarly, diarrhea and hyponatremia should prompt consideration of infection with *Legionella* species.[66] Additional pathogen-specific considerations are discussed later in this chapter.

While important, the pulmonary physical exam is plagued by poor interrater reliability. In a study of 52 patients presenting to an ED with symptoms of lower respiratory tract infection (of whom 24 were ultimately diagnosed with pneumonia), only the identification of rales and wheezes reached even fair levels of agreement between independent examiners.[67] "Classic" physical exam findings of pneumonia including bronchophony and egophony had markedly poor interrater reliability. In a recent meta-analysis of 11 studies, chest auscultation was found to have a sensitivity of 0.33 (95% confidence interval [CI], 0.24–0.44), specificity of 0.87 (95% CI, 0.81–0.92), positive likelihood ratio of 2.6 (95% CI, 1.9–3.4), negative likelihood ratio of 0.77 (95% CI, 0.68–0.87), and an area under the curve of 0.68 (95% CI, 0.64–0.72).[68]

■ Imaging

The chest radiograph has long been the standard imaging modality for patients with suspected CAP. However, disagreement on radiograph interpretation, even among experienced radiologists, is well described. As an example, in a study of 282 patients with clinical CAP, agreement between two university radiologists on the presence of infiltrate was only fair ($\kappa = 0.37$; 95% CI, 0.22–0.52).[69]

Evidence supports an expanding role for computed tomography (CT) in the evaluation of patients with suspected CAP. In a secondary analysis of the CDC EPIC study, 3% of patients had radiographic evidence of CAP identified only on chest CT.[70] These patients had similar illness severity scores, bacterial infection rates, and outcomes compared with patients who had infiltrates identified on chest radiograph. Similarly, in a study of 319 patients presenting to an ED with suspected CAP, 33% of those with a negative chest radiograph were found to have an infiltrate on CT.[71] Conversely, among the 188 patients with an infiltrate identified on chest radiograph, pneumonia was excluded by chest CT in nearly 30%. Across the study cohort, CT findings frequently prompted changes in antibiotic therapy. Together, these studies support the role of chest CT in the evaluation of CAP for patients where diagnostic uncertainty persists after initial evaluation.

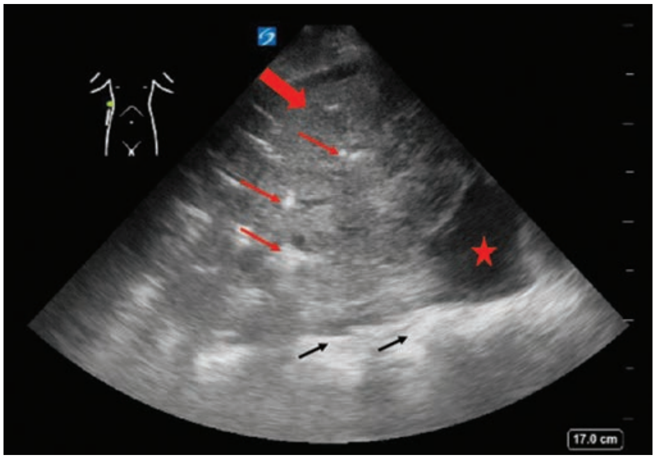

Figure 128-5 Point-of-care thoracic ultrasound image from a patient with severe community-acquired pneumonia showing dense pulmonary consolidation *(thick red arrow)*. The lung is filled with numerous hyperechoic *(bright)* areas also referred to as sonographic air bronchograms thought to represent air trapped in small airways within an area of consolidation *(thin red arrows)*. A small anechoic pleural effusion is visible *(red star)*, as are the hyperechoic spinous processes *(black arrows)*.

Enthusiasm for point-of-care ultrasound (POCUS) has increased markedly in recent years. The use of POCUS to guide safe bedside procedures and inform the rapid evaluation of patients with respiratory failure and shock is now widely considered standard of care.[72] Lung ultrasound offers a number of advantages over traditional imaging techniques including its low cost, the fact that it can be performed by the treating clinician facilitating real-time integration of imaging findings into a patient's care plan, avoidance of radiation or iodinated contrast, and the ease with which it can be performed serially over a patient's hospital stay (Fig. 128-5). A recent systematic review and meta-analysis evaluated 16 studies to determine the accuracy of lung ultrasound for diagnosing pneumonia.[73] Pooled sensitivity and specificity were not evaluated given study heterogeneity. The sensitivity of lung ultrasound ranged from 57% to 100% and specificity from 54% to 99%. While more research is needed to refine guidance on the use of lung ultrasound in pneumonia, experienced sonographers should be encouraged to incorporate lung ultrasound into their bedside evaluation, especially for acutely ill patients.[74] For additional discussion of thoracic ultrasound, the reader is referred to Chapter 29.

■ Microbiologic Evaluation

Table 128-2 summarizes IDSA–ATS guidelines on recommended diagnostic testing in CAP. Major changes between the 2007 and 2019 guidelines are summarized in Table 128-3.

Expectorated Sputum

One of the most controversial aspects of CAP diagnosis is the value of expectorated sputum. For infection with certain pathogens including *S. pneumoniae*, *H. influenzae*, and *S. aureus*, the specificity of high-quality Gram stain exceeds 85%.[75] When Gram stain shows a predominant morphotype, a causative organism is identified on culture in more than 85% of cases.[76]

TABLE 128-2 Recommendations for Diagnostic Testing from the 2019 IDSA/ATS Guidelines for Community-acquired Pneumonia

Diagnostic Test	Not Recommended	Recommend For
Pretreatment Gram stain and culture	CAP managed in the outpatient setting	• Severe CAP • Patients receiving empiric treatment for *Pseudomonas aeruginosa* or MRSA • Patients with prior infection with *P. aeruginosa* or MRSA • Patients who have been hospitalized and received parenteral antibiotics (whether during the hospitalization or not) in the last 90 days
Blood culture	CAP managed in the outpatient setting	• Severe CAP • Patients receiving empiric treatment for *P. aeruginosa* or MRSA • Patients with prior infection with *P. aeruginosa* or MRSA • Patients who have been hospitalized and received parenteral antibiotics (whether during the hospitalization or not) in the last 90 days
Legionella and pneumococcal urinary antigen testing	Most cases of CAP	• Where indicated by epidemiologic factors (such as in association with a *Legionella* outbreak or travel) • Severe CAP
Testing respiratory sample for influenza virus	CAP when there is low or no influenza circulation in the community	• When influenza is circulating in community (use of a rapid influenza molecular assay is recommended)
Procalcitonin	All patients with CAP	• Not recommended for use

ATS, American Thoracic Society; CAP, community-acquired pneumonia; IDSA, Infectious Disease Society of America; MRSA, methicillin-resistant Staphylococcus aureus.
Data from Metlay JP, Waterer GW, Long AC, et al. Diagnosis and Treatment of Adults with Community-acquired Pneumonia. An Official Clinical Practice Guideline of the American Thoracic Society and Infectious Diseases Society of America. Am J Respir Crit Care Med. 2019;200(7):e45–e67.

Despite these impressive results when testing is performed in dedicated and highly experienced microbiology laboratories, clinical results fall far short of these ideal situations. In the CDC EPIC study, a high-quality sample was obtained in only 12% of patients.[37] Even for patients with bacteremic CAP, the yield of sputum culture is variable. In a study of 1669 patients with CAP, 133 (8.0%) of whom had pneumococcal bacteremia, only 39 (29.3%) produced a high-quality sputum sample.[76] Just 13 of these samples (representing 9.8% of patients with pneumococcal bacteremia) were culture-positive for *S. pneumoniae*.

At least three reasons explain these less robust results in clinical practice: (1) many CAP etiologies are not associated with a productive cough, (2) many patients are unable to expectorate an adequate volume of sputum for a high-quality sample, and (3) emphasis

TABLE 128-3 Key Changes Between the 2007 and 2019 IDSA/ATS Guidelines for Community-acquired Pneumonia

Recommendation	2007 Guidelines	2019 Guidelines
Sputum culture	Recommended in patients with severe disease	Recommended in patients with severe disease and inpatients empirically treated for MRSA or *Pseudomonas aeruginosa*
Blood culture	Recommended in patients with severe disease	Recommended in patients with severe disease and inpatients empirically treated for MRSA or *P. aeruginosa*
Macrolide monotherapy	Strong recommendation for outpatients	Conditional recommendation for outpatients based on local resistance levels
Use of procalcitonin	Not covered	Recommend against use
Use of corticosteroids	Not covered	May be considered in patients with refractory septic shock
Use of healthcare-associated pneumonia	Accepted as a categorization	Recommend abandoning this categorization; emphasis on local epidemiology and validated risk factors to determine need for MRSA or *P. aeruginosa* coverage; increased emphasis on de-escalation of treatment if cultures are negative
Standard empiric therapy for severe CAP	β-Lactam/macrolide and β-lactam/fluoroquinolone combinations given equal weight	Both accepted but stronger evidence in favor of β-lactam/macrolide combination
Routine use of follow-up chest imaging	Not covered	Recommend not to obtain; patients may be eligible for lung cancer screening, which should be performed as clinically indicated

ATS, American Thoracic Society; CAP, community-acquired pneumonia; IDSA, Infectious Disease Society of America; MRSA, methicillin-resistant Staphylococcus aureus.

on time to first antibiotic dose means that many samples are not obtained until after exposure to antibiotics. For *S. pneumoniae* and *H. influenzae*, even a single dose of antibiotic results in negative cultures. Additionally, whether sputum Gram stain and culture routinely alters management or impacts patient outcomes is unclear.[77,78]

The most recent IDSA–ATS guidelines re-emphasize the value of sputum Gram stain and culture for reasons of antibiotic stewardship. Sputum samples are recommended specifically for patients in whom broad-spectrum antibiotics are being considered due to sufficient clinical concern for infection with a pathogen resistant to usual CAP antibiotic regimens. Infection with many of these bacterial pathogens, including *P. aeruginosa* and MRSA, are more likely to result in a productive cough, are less likely to be suppressed on culture with early empiric antibiotics, and are more likely to alter management if identified on culture. Even with these recommendations, assuring that the sputum sample is free from upper airway contamination is critical. In general, fewer than 10 squamous epithelial cells per low-power field are required for an informative sample.

The equation may be changing significantly with the development of molecular diagnostics. PCR-based assays can detect pathogens killed by recently administered antibiotics and are routinely more sensitive than culture from the same sample. In addition, the clinical diagnostic standard for several bacterial pathogens that require very specialized culture media and conditions for growth, including *Legionella*, *Mycoplasma*, and *Chlamydia*, is already PCR. A multiplex PCR of high-quality specimens in the CDC EPIC study had a very high yield for a variety of bacteria, as well as viruses, missed by nasopharyngeal swab.[79] Commercially available multiplex platforms have been validated on expectorated sputum.[80,81]

Reluctance to culture should not apply to tracheal aspirates from patients with severe CAP.[82] While tracheal aspirates facilitate sampling of the lower respiratory tract, negative cultures resulting from recent antibiotics are still common. However, a negative culture from a tracheal aspirate specimen effectively rules out resistant bacterial pathogens and allows antibiotic de-escalation. Once again, multiplex PCR solves some of these issues.

Blood Cultures

The yield of blood cultures when obtained broadly in patients with CAP is low, with positivity rates ranging from 0% to 14% depending on the study population.[83] In the CDC EPIC study, 119 (5.8%) of the 2069 blood cultures obtained were positive.[37] Significantly higher positivity rates were noted when cultures were obtained prior to the administration of antibiotics. Regardless of the result, blood cultures infrequently alter management for patients with CAP.[83] Accordingly, blood cultures are recommended only for patients with severe disease or with concern for infection with a drug-resistant pathogen.

Legionella and Pneumococcal Antigen Testing

Urinary antigen testing can identify pathogen-specific capsular polysaccharides for *L. pneumophila* and *S. pneumoniae*. For *L. pneumophila*, commercially available assays only identify infection with serogroup 1. Fortunately, this serogroup is responsible for more than 80% of *L. pneumophila* infections in most areas of the United States.[84] In a systematic review and meta-analysis of 30 studies, urinary antigen testing for serogroup 1 had a pooled sensitivity of 0.74 (95% CI, 0.68–0.81) and specificity of 0.99 (95% CI, 0.98–1.0).[85] When obtained routinely in patients with CAP, positivity rates for *L. pneumophila* urinary antigen tests are low. In the CDC EPIC study, 1.6% of patients had a positive *Legionella* antigen test.[37] Similarly, in a multicenter prospective cohort of 1941 patients hospitalized with CAP, 32 (1.6%) had a positive urinary antigen test for *L. pneumophila*.[86]

Notably, in a recent large retrospective review, 23% of patients found to have *Legionella* CAP did not receive empiric antibiotics that covered *Legionella*, highlighting the potential role of antigen testing to inform early therapy, especially for patients not receiving empiric coverage for *L. pneumophila*.[66] IDSA–ATS guidelines recommend urinary antigen testing for *L. pneumophila* only for patients with severe CAP or when there are clear epidemiologic risk factors for *L. pneumophila* infection.

As with *Legionella*, urinary antigen testing for *S. pneumoniae* is highly specific. In a meta-analysis of 27 studies, urinary antigen testing for *S. pneumoniae* had a sensitivity of 74.0% (95% CI, 66.6%–82.3%) and specificity of 97.2% (95% CI, 92.7%–99.8%).[87] False positives can result from recent pneumococcal vaccination. Urinary antigen testing for *S. pneumoniae* is appealing as it is inexpensive and quick to process, and results are unaffected by recent antibiotic administration. IDSA–ATS guidelines recommend urinary antigen testing for *S. pneumoniae* only for patients with severe CAP. Notably, recent data suggest that as few as 18% of critically ill patients with pneumonia undergo urinary antigen testing for *S. pneumoniae*.[88] Narrowing this implementation gap has the potential to significantly impact antimicrobial stewardship.[89]

PCR-based Testing

As noted above, nucleic acid amplification using PCR is now the testing method of choice to identify respiratory viral pathogens in patients with CAP. PCR allows for the exponential amplification of a target DNA sequence.[90] RT-PCR (where RNA rather than DNA is used as the starting material for PCR) is used for detection of RNA viruses.

PCR-based testing is appealing for a number of reasons. With multiplex platforms, multiple patient samples can be quickly tested for clinically relevant pathogens, facilitating both rapid diagnosis and the identification of polymicrobial infections. Many platforms are semi- or even fully automated, obviating the need for more than basic laboratory personnel. Results are typically available in a matter of hours, enabling rapid pathogen detection for acutely ill patients. Perhaps most importantly, PCR-based testing is both highly sensitive and specific.[91]

Despite these advantages, how and when to incorporate molecular diagnostic testing for respiratory viruses in CAP remains a source of debate. IDSA–ATS guidelines recommend testing for influenza virus with a nucleic acid amplification assay when influenza virus is circulating in the community but do not comment on testing for other respiratory viruses.

Several challenges with PCR-based testing for respiratory viruses deserve mention. First, sensitive diagnostic platforms are unable to distinguish between true infection and asymptomatic viral carriage. Rates of asymptomatic viral carriage range from 2% to 17% depending on the patient population studied.[37,92–94] Second, results from upper and lower respiratory tract samples are frequently discordant.[50,95] In a study of patients admitted to the ICU with acute respiratory failure, 20% of patients with a severe respiratory infection had a viral pathogen identified only in the upper airway while 29% had a virus identified exclusively on tracheobronchial aspirate.[93] Third, bacterial and viral coinfection is common, occurring in more than one-third of cases.[37,96] The identification of a viral pathogen on PCR-based testing, therefore, does not guarantee the safety of withholding or discontinuing antibiotic therapy for CAP. Finally, the use of molecular diagnostic platforms has not yet been convincingly shown to improve clinical outcomes.[97]

A growing number of multiplex platforms now identify bacteria and genes associated with antibiotic resistance (e.g., *mecA* for MRSA). Early studies suggest that these tests may facilitate the detection of bacterial pathogens in CAP and aid antimicrobial stewardship.[98,99] These expanded assays may prove particularly useful in intubated patients with severe CAP where the rapid testing of lower respiratory tract specimens may aid the timely identification and treatment of drug-resistant pathogens. To date, no large trials have evaluated the safety and efficacy of diagnosing and treating severe CAP using PCR-based diagnostic platforms.

Procalcitonin

Procalcitonin, a protein produced in health by thyroid neuroendocrine cells and synthesized by most tissues during bacterial infection, is a promising biomarker to guide antibiotic therapy for patients with respiratory infections and sepsis.[100] When evaluated broadly in patients with "acute respiratory infections," procalcitonin-guided antibiotic therapy decreases exposure to antibiotics and lowers mortality.[101] However, in a recent systematic review and meta-analysis focused only on patients with CAP, procalcitonin (at a level of 0.5 μg/L) did not reliably distinguish between bacterial and viral infection.[102] A recent multicenter trial of 1656 patients presenting to the ED with suspected lower respiratory tract infection found that providing clinicians a procalcitonin level and guidance on test interpretation failed to decrease antibiotic use, although multiple protocol violations complicate interpretation of these results.[103]

IDSA–ATS guidelines recommend against using procalcitonin to guide the initiation of empiric antibiotic therapy for patients with CAP. Whether pairing procalcitonin with PCR-based multiplex testing for respiratory viruses can inform the safe discontinuation of antibiotics for patients with viral CAP is an important area for future study.[49]

■ Risk Stratification

Appropriate decisions regarding the site of care have a major impact on the cost of care and may impact mortality. Hospitalization clearly plays a major role in the cost of care, although inappropriate floor admission of critically ill patients is associated with both increased cost and mortality.

Inpatient Versus Outpatient Care

Guidelines recommend the use of a validated clinical prediction tool in addition to clinical judgment to inform which patients with CAP should be hospitalized. Of available scoring systems, the *pneumonia severity index* (PSI) has the most robust supporting evidence and is the tool recommended by the IDSA–ATS.

The PSI was developed in 1997 as a mortality prediction tool for patients with CAP.[104] Based on 20 prognostic variables, patients are grouped into one of five risk classes (Table 128-4). In general, patients in risk classes IV and V are classified as high-risk and should be hospitalized. Rigorous randomized controlled trials demonstrate that integration of the PSI into decision-making pathways increases the number of patients who can be safely managed in the outpatient setting.[105] Proponents of the PSI highlight the score's slightly superior test characteristics for identifying low-risk patients and predicting 30-day mortality.[106] Complexity at the point of care limits clinical use.

CURB-65, the major alternative scoring system, is preferred by many for its simplicity as it contains only five variables (confusion, blood urea nitrogen >20 mg/dL, respiratory rate ≥30 breaths per minute, systolic blood pressure <90 mm Hg or diastolic blood pressure ≤60 mm Hg, and age ≥65 years of age). Patients with a score of 0 to 2 are classified as low-risk and have 30-day mortality rates less than or equal to 2.1%.[105] The British Thoracic Society recommends CURB-65 over the PSI in part due to ease of use.[107] The simplicity of CURB-65 allows better integration into electronic site-of-care decision support and helps reduce admission of low-risk patients.

Regardless of the prediction tool used, clinicians should remember that these scores are meant to support rather than replace clinical judgment. Important considerations including barriers to safe longitudinal care after discharge, the severity of comorbid illness, and the magnitude of vital sign abnormalities relative to a patient's baseline may provide compelling reasons for admission irrespective of a patient's risk score.

TABLE 128-4 Pneumonia Severity Index

Patient Characteristic	Points Assigned
Demographic factors	
Males	Age (years)
Females	Age (years) – 10
Nursing home residents	Age (years) + 10
Comorbid illnesses	
Neoplastic disease	+30
Liver disease	+20
Congestive heart failure	+10
Cerebrovascular disease	+10
Renal disease	+10
Physical examination findings	
Altered mental status	+20
Respiratory rate ≥30 breaths/min	+20
Systolic blood pressure <90 mm Hg	+20
Temperature <35°C or ≥40°C	+15
Pulse ≥125 beats/min	+10
Laboratory findings	
pH <7.35	+30
Blood urea nitrogen ≥30 mg/dL	+20
Sodium <130 mEq/L	+20
Glucose ≥250 mg/dL	+10
Hematocrit <30%	+10
Partial pressure of oxygen <60 mm Hg	+10
Pleural effusion	+10

Interpretation: Patients <50 years of age who do not have any of the above comorbid illnesses or physical examination findings are risk class I; patients with a score of ≤70 are risk class II; patients with a score of 71–90 are risk class III; patients with a score of 91–130 are risk class IV; and patients with a score of >130 are risk class V. Risk classes I and II are felt appropriate for outpatient care, while risk classes IV and V should be hospitalized. Disposition for patients in risk class III should be guided by clinician judgment.

Data from Fine MJ, Auble TE, Yealy DM, et al. A prediction rule to identify low-risk patients with community-acquired pneumonia. N Engl J Med. 1997;336(4):243–250.

Admission to the ICU

A key limitation of both the PSI and CURB-65 is their low sensitivity and specificity for predicting the need for ICU admission.[108] As such, neither score is recommended to determine the location of inpatient care. Accurate identification of patients likely to require ICU admission is critical, as delayed admission to the ICU has consistently been associated with increased mortality.[32,109]

Several scoring systems are available to guide the need for ICU admission. Of these, the 2007 IDSA–ATS major and minor criteria for severe CAP are recommended for use in IDSA–ATS guidelines (Table 128-5). As the major criteria (need for mechanical ventilation or vasopressor support) are self-evident indications for ICU admission, the minor criteria have been proposed as a stand-alone risk-stratification tool. A large prospective validation study of 1062 patients with CAP in the United Kingdom found the presence of greater than or equal to 3 IDSA–ATS minor criteria to be predictive of the need for mechanical ventilation or vasopressors (area under the receiver operator characteristic curve [AUC], 0.85; 95% CI,

TABLE 128-5 Criteria for Severe Community-acquired Pneumonia

Minor criteria[a]	• Respiratory rate ≥30 breaths/min[b] • PaO_2/FiO_2 ≤250[b] • Multilobar infiltrates • Confusion/disorientation • Uremia (BUN ≥20 mg/dL) • Leukopenia (WBC count <100,000 cells/mm^3)[c] • Hypothermia (core temperature <36 °C) • Hypotension requiring aggressive fluid resuscitation
Major criteria	• Invasive mechanical ventilation • Septic shock with need for vasopressors

[a] *Other criteria to consider include hypoglycemia (in nondiabetic patients), acute alcoholism/alcohol withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.*

[b] *A need for noninvasive ventilation can substitute for a respiratory rate >30 breaths/min or* Pa_{O_2}/Fi_{O_2} *≤250.*

[c] *As a result of infection alone.*

Severe pneumonia is defined as the presence of at least one major or three or more minor criteria.

BUN, blood urea nitrogen; Pa_{O_2}/Fi_{O_2}*, arterial oxygen pressure/fraction of inspired oxygen; WBC, white blood cell.*

0.82–0.88) and ICU admission (AUC 0.85; 95% CI, 0.82–0.88).[110] Use of these criteria to identify at-risk patients in the ED may reduce delayed ICU admission and improve clinical outcomes, although more studies are needed to confirm these findings.[111]

The development and validation of decision tools to identify patients most likely to benefit from ICU admission is complicated by a number of factors including how scores consider limitations in care (e.g., do not resuscitate orders) and the significant variation in center-specific factors that impact ICU bed utilization.[108]

■ Empiric Antibiotic Therapy

Empiric antibiotic therapy for CAP should provide robust coverage of common pathogens while minimizing the harms associated with the overuse of broad-spectrum antibiotics. Factors that inform antibiotic selection include the severity of illness and the presence of risk factors for drug-resistant pathogens. IDSA–ATS recommendations for empiric antibiotic therapy for patients with CAP are summarized in Table 128-6.

Outpatient Setting

The major change between the 2007 and the 2019 IDSA–ATS guidelines with respect to CAP managed in the outpatient setting is the downgrading of the strength of recommendation for macrolide monotherapy in healthy patients without comorbidities from a strong recommendation to a conditional recommendation informed by local resistance levels.

S. pneumoniae and *H. influenzae* are important causes of CAP in outpatients, neither of which is reliably covered by macrolides. Pneumococcal resistance to macrolides develops through either ribosomal methylation or efflux of the drug from bacteria.[112] Resistance rates vary significantly by country but have been reported to exceed 30% in U.S. isolates.[113,114] Frequent use of macrolides for both the acute and chronic treatment of chronic lung diseases like COPD may accelerate the spread of macrolide-resistant pneumococcus in the near future. Macrolides are also generally ineffective against *H. influenzae* due to the presence of an intrinsic efflux pump. IDSA–ATS guidelines suggest macrolide monotherapy should not be used when local rates of pneumococcal resistance to macrolides exceeds 25%. Some experts suggest this cutoff should be significantly lower to minimize the risk of ineffective early antibiotic therapy for patients with CAP.[115]

Single-agent amoxicillin, while lacking activity against atypical pathogens, achieves success rates comparable to other antibiotic classes in the treatment of CAP in the outpatient setting.[116] Updated IDSA–ATS guidelines include high-dose amoxicillin (1 g three times a day) as a reasonable treatment option for healthy outpatients with CAP.

Empiric antibiotic therapy should be expanded for outpatients with comorbidities including chronic heart, lung, liver, or renal

TABLE 128-6 Antibiotic Treatment Recommendations for Community-acquired Pneumonia

Group	Antibiotic Regimens

Healthy outpatients without risk factors for MRSA or *Pseudomonas aeruginosa*[a]	• Monotherapy with
	  • Amoxicillin
	  • Doxycycline
	  • Macrolide[b,c]

Outpatients with comorbidities[d]	• Combination therapy with
	  • Amoxicillin/clavulanate or cephalosporin + Macrolide[c] or doxycycline
	  • Monotherapy with a respiratory fluroquinolone[e]

Inpatients with non-severe CAP without risk factors for MRSA or *P. aeruginosa*[a]	• Combination therapy with
	  • β-lactam[f] + macrolide[c]
	• Monotherapy with
	  • Respiratory fluroquinolone[e]
	• Combination therapy with a β-lactam[f] + doxycycline can be considered if contraindications to both macrolides and fluroquinolones

Severe CAP	• Combination therapy with
	  • β-lactam[f] + macrolide[c] *or*
	  • β-lactam + respiratory fluoroquinolone[e]

Empiric treatment for MRSA	• Vancomycin or linezolid
Empiric treatment for *P. aeruginosa*	• Piperacillin-tazobactam, cefepime, ceftazidime, aztreonam, meropenem, or imipenem

[a] *Risk factors include: prior respiratory isolation of methicillin-resistant Staphylococcus aureus or Pseudomonas aeruginosa, recent hospitalization with receipt of parenteral antibiotics during the previous ninety days.*

[b] *Macrolide therapy recommended only if local pneumococcal resistance is <25%.*

[c] *Azithromycin or clarithromycin.*

[d] *Notable comorbidities include chronic heart, lung, liver, or renal disease, diabetes mellitus, alcohol use disorder, malignancy, or asplenia.*

[e] *Levofloxacin or moxifloxacin.*

[f] *Ampicillin/sulbactam, cefotaxime, ceftriaxone, or ceftaroline.*

ATS, American Thoracic Society; CAP, community-acquired pneumonia; IDSA, Infectious Disease Society of America; MRSA, methicillin-resistant Staphylococcus aureus.

Data from Metlay JP, Waterer GW, Long AC, et al. Diagnosis and Treatment of Adults with Community-acquired Pneumonia. An Official Clinical Practice Guideline of the American Thoracic Society and Infectious Diseases Society of America. Am J Respir Crit Care Med. 2019;200(7):e45–e67.

disease; patients with diabetes mellitus; alcohol use disorder; malignancy; or asplenia. Patients with these conditions experience increased morbidity and mortality with infection and are more likely to be infected with methicillin-sensitive *S. aureus* and Gram-negative bacilli.

For outpatients with comorbidities, monotherapy with a respiratory fluoroquinolone continues to receive a strong recommendation in recent guidelines. This recommendation is supported by a strong body of evidence showing that respiratory fluroquinolones compare favorably with β-lactam or macrolide-based treatment regimens.[117] However, growing concerns about the adverse effects of fluoroquinolones, which range from tendinopathy and aortopathies to psychiatric diseases, hypoglycemia, and neuropathy, have tempered enthusiasm for this therapy.[118] Accordingly, a growing number of antimicrobial stewardship interventions aim to limit their use.[119] Fluroquinolones may be particularly problematic in areas with a high incidence of *Mycobacterium tuberculosis* (mTB). Fluoroquinolones are effective anti-mTB agents, and their use for suspected bacterial CAP may impede a timely diagnosis of mTB infection.[115]

Anaerobic Coverage

IDSA–ATS guidelines now explicitly recommend against the addition of anaerobic coverage for patients with aspiration pneumonia in the absence of lung abscess or empyema (conditional recommendation, very low quality of evidence). This recommendation is driven by the changing microbiology of aspiration pneumonia. While historic studies describe high rates of infection with anaerobic pathogens, confirmation of an anaerobic infection is now increasingly uncommon.[120] In a recent secondary analysis of the GLIMP study, 2606 hospitalized patients with CAP were evaluated for a diagnosis of aspiration pneumonia, the presence of aspiration risk factors, and the results of microbiologic evaluation.[121] Only 0.5% of patients with aspiration pneumonia and 0.3% of patients with CAP and aspiration risk factors had an anaerobic pathogen isolated from respiratory samples. Despite this, 16% of patients with aspiration CAP and 5% of patients with CAP and no aspiration risk factors received anaerobic coverage, highlighting an important area for improved antimicrobial stewardship.

Inpatient Setting

An ongoing debate in the management of hospitalized patients with nonsevere CAP concerns the safety and efficacy of monotherapy with a β-lactam. Indeed, the key distinction between IDSA–ATS guidelines and those from countries in northern Europe is the strong recommendation for β-lactam–macrolide combination therapy in North American guidelines.

The strongest supporting evidence for β-lactam monotherapy comes from a 2015 multicenter cluster-randomized trial of 656 hospitalized patients with nonsevere CAP in the Netherlands.[122] β-Lactam monotherapy was found to be noninferior to β-lactam–macrolide combination therapy with respect to the primary endpoint of 90-day mortality. Several caveats have been raised about the generalizability of these findings. First, many patients enrolled in the study had a low severity of illness, roughly 25% did not have radiographically confirmed CAP, and protocol deviations were high and occurred differentially among the regimens. Second, patients were hospitalized for a median of 6 days, twice as long as comparable North American trials.[123] This added period of observation may have facilitated prompt recognition of treatment failure with β-lactam monotherapy (which actually occurred in a substantially greater proportion of patients initially treated with β-lactam monotherapy). Finally, it is debatable whether empiric antibiotic selection in nonsevere CAP can impact 90-day mortality—a metric that is likely driven predominately by comorbid conditions.

In contrast, a 2014 multicenter randomized trial of 291 patients hospitalized with CAP in Switzerland found β-lactam monotherapy to be associated with lower rates of clinical stability at day 7.[124] Additionally, patients treated with combination therapy experienced lower serious adverse events while hospitalized and lower 30-day readmission rates. In a 2016 systematic review, 6 of 8 included observational studies reported lower short-term mortality rates with β-lactam–macrolide combination therapy.[125]

The addition of a macrolide to β-lactam therapy may improve outcomes through several mechanisms including coverage of atypical pathogens, nonbactericidal immunomodulatory effects, and suppression of the exotoxin pneumolysin production when infection is caused by *S. pneumoniae*.

Monotherapy with a respiratory fluoroquinolone for hospitalized patients with nonsevere CAP continues to receive a strong recommendation in IDSA–ATS guidelines despite the concerns regarding fluoroquinolones noted above. In support of this recommendation, observational studies have reported relative reductions in mortality of 30% to 45% with the use of fluoroquinolones compared to β-lactam monotherapy for hospitalized patients with CAP.[125]

Severe CAP

Empiric antibiotic therapy for patients with severe CAP remains a significant challenge. No prospective trials have studied the efficacy and safety of different antibiotic regimens for severe CAP. This paucity of data is troubling, as patients with severe CAP have high rates of infection with difficult-to-treat pathogens including MRSA, *P. aeruginosa*, and Enterobacterales. Additionally, critically ill patients are the most likely to experience significant morbidity and mortality with even small delays in administration of appropriate antibiotic therapy.[126]

In the absence of risk factors for drug-resistant pathogens, patients with severe CAP should receive combination therapy with either a β-lactam and a macrolide or a β-lactam and a respiratory fluroquinolone. These recommendations are based on the benefit of combination therapy noted in observational studies. In a 2014 meta-analysis of 28 studies involving 9850 critically ill patients with CAP, therapy with a macrolide was associated with a 3% absolute risk reduction in mortality compared with non-macrolide-containing regimens (21% vs. 24%; risk ratio [RR], 0.82; 95% CI, 0.70–0.97).[127] The addition of a macrolide appears to improve outcomes in severe pneumococcal CAP independent of macrolide resistance rates, possibly due to its antitoxin effects.[128]

Antibiotics for Drug-resistant Pathogens

As discussed above, a major change in recent IDSA–ATS guidelines is the recommendation to abandon HCAP as a clinically relevant phenotype given its unacceptably low positive predictive value for infection with drug-resistant pathogens. Instead, guidelines highlight the importance of using locally validated risk factors to identify patients likely to benefit from empiric therapy against MRSA and *P. aeruginosa*. When local risk factors are not available, guidelines recommend empiric broad-spectrum antibiotics for patients with a history of MRSA or *P. aeruginosa* infection within the past year regardless of disease severity. Additionally, broad-spectrum antibiotics should be administered to patients with severe CAP and a history of hospitalization with exposure to parenteral antibiotics within the past 90 days. Guidelines support the use of an MRSA nasal swab to inform de-escalation of MRSA coverage. In a 2018 meta-analysis, a negative MRSA nasal swab was found to have a negative predictive value greater than 98% for patients with CAP.[129] Given its much lower positive predictive value (56.8%), the implications of a positive MRSA nasal swab are less clear.

While vancomycin and linezolid are equally recommended as empiric treatment options for MRSA, linezolid therapy or inclusion of clindamycin with vancomycin for likely exotoxin-expressing strains, such as the USA300 strain, are associated with lower mortality rates.[130] Although piperacillin–tazobactam, cefepime, ceftazidime, aztreonam, meropenem, and imipenem are included as reasonable empiric options to coverage *P. aeruginosa* and other Gram-negative pathogens, a variety of studies suggest that outcomes with these broader spectrum β-lactams are less effective for more common CAP pathogens.

A limitation of current guidelines is their exclusive focus on the identification and treatment of CAP secondary to MRSA and *P. aeruginosa*. Especially for patients with severe CAP, infection with ESBL-producing Enterobacterales and *A. baumannii* also are important diagnostic considerations.[53] Better predictive tools are needed to aid clinicians in identifying patients most likely to benefit from empiric therapy that covers these pathogens. Testing of lower respiratory tract samples with multiplex PCR-based diagnostic platforms is a promising yet understudied approach that may aid the prompt identification of infection with drug-resistant pathogens and inform the safe de-escalation of empiric broad-spectrum antibiotic therapy for patients with severe CAP.

Novel Antibiotics

The increasing prevalence of drug-resistant pathogens in CAP highlights the need to expand our antibiotic armamentarium. In recent years, only one antibiotic with an entirely novel mechanism of action has been approved by the U.S. Food and Drug Administration for CAP. Lefamulin is a semisynthetic pleuromutilin that inhibits the 50S subunit of bacterial ribosomes. In a recent phase 3 clinical trial, 5 days of lefamulin was found to be noninferior to a 7-day course of moxifloxacin for the primary endpoint of early clinical response at 96 h.[131]

Other recently approved antibiotics expand upon already available drug classes. Omadacycline, a once-daily aminomethylcycline derived from the tetracycline class, was found to be noninferior to moxifloxacin for the treatment of CAP.[132] Ceftaroline fosamil, a cephalosporin with activity against MRSA and many Gram-negative pathogens, performed favorably against ceftriaxone in hospitalized patients with nonsevere CAP.[133] More research is needed to inform when and if these medications should be used in routine care.

■ Antiviral Therapy

IDSA–ATS guidelines recommend the use of oseltamivir for patients with CAP and confirmed influenza infection in both the inpatient and outpatient setting independent of the duration of illness prior to diagnosis.

The role of neuraminidase inhibitors for patients with influenza infection is controversial. A 2014 Cochrane Group review found that the use oseltamivir in healthy outpatients was associated with a 16.8-h reduction in time to first alleviation of symptoms (95% CI, 8.4–25.1) compared with placebo.[134] However, therapy did not significantly reduce hospitalization rates or serious complications of influenza and came with increased rates of gastrointestinal, renal, and psychiatric adverse effects. A patient-level meta-analysis of more than 3000 patients from 9 countries with influenza A (H1N1) virus infection found that treatment with a neuraminidase inhibitor was associated with decreased odds of hospital admission (adjusted OR, 0.24; 95% CI, 0.20–0.30).[135] A more recent meta-analysis of more than 18,000 patients with influenza A (H1N1) virus infection found that the use of neuraminidase inhibitors was associated with reduced hospital length of stay.[136] How reliably conclusions from studies evaluating the efficacy of neuraminidase inhibitors in a broadly defined population of outpatients can be extrapolated to the subset of patients with confirmed CAP is unclear.

No randomized trials of neuraminidase inhibitors in critically ill patients with CAP secondary to influenza infection exist. Pooled data from observational trials suggest that prompt therapy with neuraminidase inhibitors is associated with improved outcomes including lower mortality rates.[137]

Patients with CAP and confirmed influenza infection should still receive empiric antibiotic therapy. Rates of bacterial coinfection in patients with influenza range from 2% to 65%, with *S. pneumoniae* and *S. aureus* being the most frequently isolated pathogens.[138] More accurate diagnosis of bacterial superinfection in severe CAP patients may ultimately change this recommendation for universal antibiotics.

■ Adjunctive Therapy: Corticosteroids

The efficacy and safety of corticosteroids in patients with CAP remain a source of debate. Several randomized clinical trials have shown corticosteroids to be associated with improved intermediate clinical endpoints. A multicenter trial in Switzerland of 785 hospitalized patients with CAP found that patients randomized to receive 50 mg of prednisone daily for 7 days experienced a shorter median time to clinical stability than patients who received placebo (3.0 days vs. 4.4 days).[139] A multicenter randomized controlled trial in Spain evaluated the impact of intravenous methylprednisolone 0.5 mg/kg given every 12 h for five days versus placebo in 120 patients with CAP and a CRP greater than 150 mg/L.[140] Patients in the intervention arm experienced a significant reduction in the primary outcome of treatment failure compared with patients in the control arm (13% vs. 31%; $p = 0.02$). However, no difference was noted in hospital length of stay, time to clinical stability, or in-hospital mortality. Additionally, the reduction in the primary endpoint was driven predominantly by less radiographic progression in patients who received steroids—a finding of unclear clinical significance.

Raising concern for the use of corticosteroids in patients with mild to moderate CAP, a recent stepped-wedge cluster-randomized clinical trial of 816 patients hospitalized with CAP of varying severities found that implementation of a bundled intervention that included adjunctive prednisolone acetate 50 mg daily for 7 days did not improve clinical outcomes and was associated with increased rates of gastrointestinal bleeding (2.2% vs. 0.7% for patients who received steroids vs. placebo, respectively).[141]

A Cochrane group meta-analysis of 13 trials in adults found corticosteroid treatment to be associated with reduced mortality in patients with severe CAP (RR, 0.58; 95% CI, 0.40–0.84) but not in adults with less severe pneumonia (RR 0.95; 95% CI, 0.45–2.00).[142] However, the methodologic rigor of several of the most positive trials included in this analysis has been questioned.[143] Results of a large Veterans Affairs study specifically addressing severe CAP, which include more patients with severe CAP than the entire Cochrane meta-analysis, are available in preliminary form and demonstrate no benefit with steroid therapy.[144]

Further clouding the role of corticosteroids in CAP is conflicting evidence on the impact of corticosteroids in viral pneumonia. In patients with pneumonia and confirmed influenza infection, the use of adjunctive corticosteroids is associated with increased mortality.[145] Conversely, corticosteroids reduce mortality for critically ill patients with COVID-19 pneumonia.[146]

IDSA–ATS guidelines recommend against the use of corticosteroids for patients with CAP regardless of severity. Guidelines do endorse the Surviving Sepsis Campaign recommendation for the use of stress-dose hydrocortisone in patients with CAP and refractory shock. For clinicians who do choose to use steroids for patients with CAP, therapy should likely be restricted to those with severe disease.[147]

■ Duration of Therapy

Patients with CAP should receive antibiotics for a minimum of 5 days, with the timing of discontinuation past this point guided by markers of clinical stability. This approach is supported by a 2016 multicenter randomized controlled trial of 312 hospitalized patients with CAP where the duration of antibiotic therapy beyond day 5 was guided by either specific markers of clinical stability (intervention arm) or clinician discretion (control arm).[148] Patients in the intervention arm had equivalent clinical outcomes despite spending significantly less time on antibiotics. Despite these recommendations, upward of one-third of patients with CAP continue to receive antibiotics for days after vital signs have normalized.[149]

■ Follow-up Imaging

Routine follow-up imaging after an uncomplicated episode of CAP is not recommended. Lung-cancer screening with low-dose chest CT should be pursued for patients who meet the eligibility criteria outlined in the U.S. Preventive Services Task Force guidelines.[150]

■ Prevention

Vaccination against *S. pneumoniae*, influenza, and now SARS-CoV-2 are the major preventative interventions to decrease the risk of CAP. The CDC's Advisory Committee on Immunization Practices (ACIP) publishes guidelines on recommended immunization schedules for both children and adults.[151]

Widespread childhood vaccination with the pneumococcal conjugate vaccine (PCV13) is thought to contribute to declining rates of invasive pneumococcal disease in both children and adults. The effectiveness of this vaccine has allowed the ACIP to reverse the recommendation that all adults older than 65 years of age receive the PCV13 vaccine. Instead, the ACIP now recommends that adults should engage in shared decision-making with their provider. PCV13 is still recommended for immunosuppressed adults and those with cerebrospinal fluid (CSF) leak or cochlear implants. All children younger than 2 years of age should still receive the PCV13 vaccine in a series of four doses. More controversial is the recommendation that adults 65 years of age and older receive the less effective purified polysaccharide vaccine (PPSV23) vaccine, which contains capsular antigens for additional capsular serotypes. Adults who received PCV23 before age 65 should receive one additional dose after age 65 administered at least 5 years after the prior dose of PCV23.

All adults, including pregnant women, should be encouraged to receive an annual influenza vaccine, the most common of which is an injection of an inactivated influenza virus. Intranasal administration of a live attenuated virus is available for adults less than 50 years of age. Contraindications to the live attenuated virus include a history of severe allergic reactions to any vaccine component, immunocompromised states, close contact with severely immunocompromised persons, pregnancy, cranial CSF–oropharyngeal communications, and cochlear implants.

Smoking cessation counseling and administration of evidence-based pharmacotherapies to aid cessation efforts are important additional preventative interventions given the clear link between smoking and pneumococcal disease.[152]

The COVID-19 pandemic has illustrated the powerful role appropriate isolation of infected individuals, masking in public places, and vaccination play in pneumonia prevention. Influenza and other respiratory viral infections have virtually disappeared during this pandemic, even in countries that had few SARS-CoV-2 cases and practiced milder forms of these preventative practices.

■ Specific Pathogens

Below we discuss common specific pathogens identified as etiologic agents in CAP.

Streptococcus pneumoniae

S. pneumoniae is still thought to be the most common bacterial cause of CAP. Fortunately, due in part to declining rates of cigarette smoking and effective vaccination programs, the burden of invasive pneumococcal disease in the United States is decreasing. In the CDC EPIC study, *S. pneumoniae* was identified in only 5% of patients.[37] Whether relaxing the adult PCV13 vaccine recommendations will maintain these lower rates is unknown.

Despite these encouraging trends, the global burden of *S. pneumoniae* remains sizeable. Pneumococcal disease is responsible for more than half of lower respiratory tract infection–related deaths in children under 5 years of age.[153] Annually, pneumococcal pneumonia causes an estimated 1.5 million deaths worldwide, including nearly 700,000 deaths in adults over 70 years of age.[153] Risk factors for pneumococcal disease include advanced age (the incidence of *S. pneumoniae* infection in adults over 65 years of age is almost 5 times higher than in younger patients), smoking, chronic respiratory disease, chronic heart disease, asplenia, diabetes mellitus, alcohol use disorder, and antecedent influenza infection.[154]

S. pneumoniae is spread from person to person either by inhalation of airborne droplets or by direct contact with respiratory secretions.[155] Asymptomatic colonization of the nasopharynx, especially in children, is felt to be an important bacterial reservoir facilitating spread throughout the community. At least 97 distinct capsular polysaccharide serotypes are known.[155] Bacterial serotype appears to be an important determinant of both the symptomology and disease severity observed with infection.[156] Indeed, emergent serotypes following widespread pneumococcal vaccination may partly explain why the incidence of complicated pneumococcal pneumonia and empyema increased globally between 1990 and 2012.[157] A number of virulence factors contribute to bacterial pathogenicity, including a polysaccharide capsule that facilitates evasion of host immune cells and production of the pore-forming exotoxin pneumolysin, which induces inflammation and promotes bacterial transmission.[155]

The classic presentation of pneumococcal CAP includes fever, purulent rust-colored sputum, pleuritic chest pain, and dense consolidation on chest radiograph (Fig. 128-6). This constellation of findings is far less common with widespread attention to early antibiotic therapy. The elderly and immunocompromised patients are more likely to present with atypical features.[158] Nearly 40% of patients with pneumococcal CAP are bacteremic on presentation.[159] The presence of a pleural effusion or a CRP greater than 20 mg/dL are predictive of bacteremia.[159] Whether bacteremic patients represent a particularly high-risk group is unclear, as studies on the prognostic significance of bacteremia have reached variable conclusions.[160,161]

S. pneumoniae can be identified on Gram stain as lancet-shaped Gram-positive diplococci grouped in pairs and short chains. While findings on Gram stain are highly specific for *S. pneumoniae*, less than 30% of patients with pneumococcal bacteremia are able to produce a high-quality sputum sample.[76] In the CDC EPIC study, only 28% of *S. pneumoniae* infections were diagnosed via analysis of expectorated sputum.[37] *S. pneumoniae* grows readily on a blood agar plate, and culture of lower respiratory tract specimens remains valuable for its ability to inform antibiotic susceptibility.

Urinary antigen testing has appealing test characteristics, with a sensitivity above 70% and a specificity approaching 100% for infection with *S. pneumoniae*.[87] This diagnostic approach can be particularly helpful in patients unable to produce a high-quality sputum sample or those who have already received antibiotics, as test characteristics are unaffected by recent therapy. An important limitation is that testing does not provide information on antibiotic susceptibility.

In 2008, the Clinical and Laboratory Standards Institute revised the minimum inhibitory concentration (MIC) breakpoints that define *S. pneumoniae* susceptibility to penicillin.[162] For infections other than meningitis, susceptibility to an intravenous penicillin is now defined by an MIC of less than or equal to 2 μg/mL and

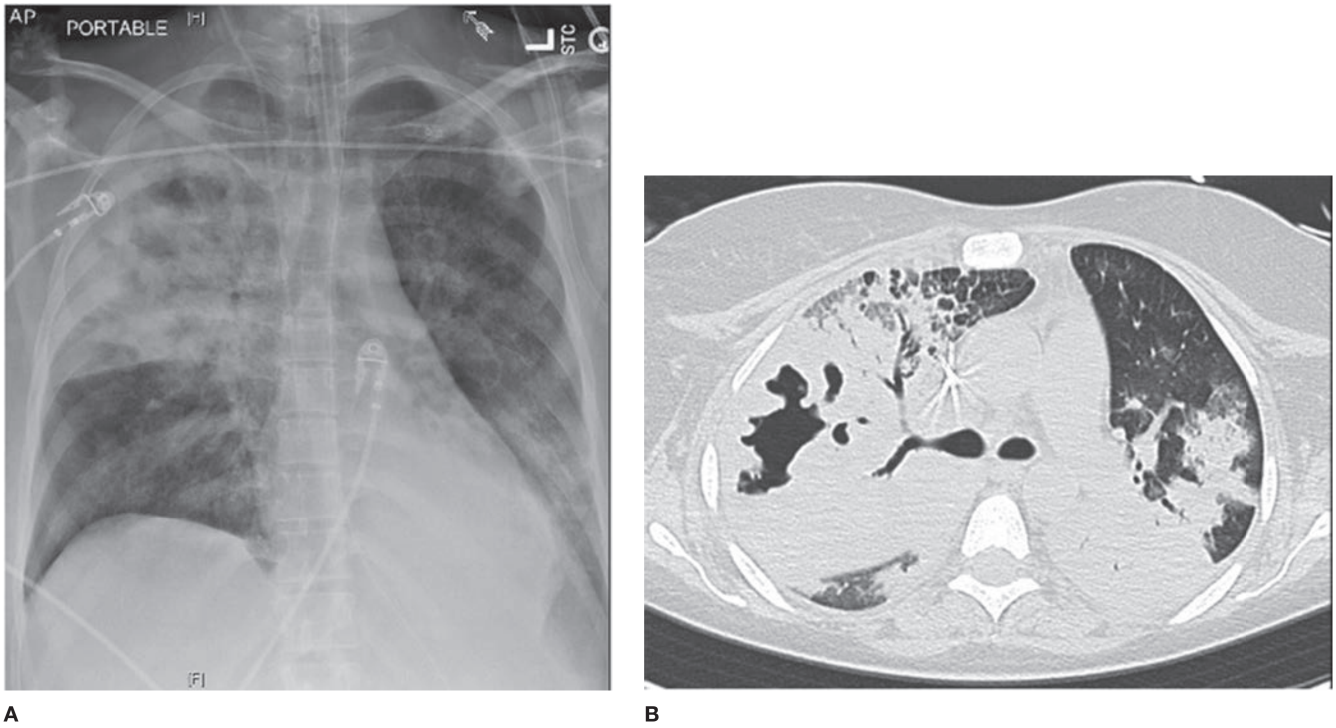

Figure 128-6 **A.** Portable chest radiograph showing dense multifocal consolidation in a patient with septic shock and hypoxemic respiratory failure secondary to *Streptococcus pneumoniae* community-acquired pneumonia. **B.** Axial chest computed tomography performed 3 days later showing persistent multifocal consolidation and evolving cavitation in the right upper lobe.

high-level resistance defined as an MIC greater than or equal to 8 μg/mL. This change has led to a decrease in the number of isolates identified as resistant to penicillin (2% in recent CDC data).[163,164]

High-dose amoxicillin is recommended as front-line therapy for healthy outpatients with CAP in recent IDSA–ATS guidelines. Ceftriaxone is the treatment of choice for hospitalized patients with pneumococcal pneumonia. In the United States, nearly 98% of pneumococcal isolates are either suspectable (MIC ≤1 μg/mL) or intermediately susceptible (MIC >1 and ≤2 μg/mL) to ceftriaxone.[164] For patients unable to receive ceftriaxone, a respiratory fluoroquinolone provides equally robust coverage although with a more concerning side-effect profile. Given the high rates of macrolide-resistant *S. pneumoniae,* studies showing a benefit to β-lactam–macrolide combination therapy in hospitalized patients with CAP suggest that the anti-inflammatory properties of macrolides may be particularly valuable. Supporting this hypothesis, in a recent study of hospitalized patients with CAP in Spain, β-lactam–macrolide combination therapy was most strongly associated with lower mortality in patients with pneumococcal pneumonia and an elevated CRP.[165]

Haemophilus influenzae

H. influenzae is a small Gram-negative coccobacillus with strains characterized as either encapsulated (serotypes a through f) or nonencapsulated/nontypeable. As a result of childhood vaccination against *H. influenzae* serotype b (Hib), the incidence of Hib disease in children has sharply declined.

In an analysis of invasive *H. influenzae* in the United States from 2009 to 2015 conducted through the CDC-supported Active Bacterial Core surveillance program, the mean annual incidence of invasive *H. influenzae* was 1.70 cases per 100,000 population.[166] The highest incidence was in very young children and adults over the age of 65, with a disproportionate burden of disease noted in American Indians and Alaska Natives. Nearly 80% of strains identified in older patients were nontypeable. During the study period, the incidence of *H. influenzae* increased, driven largely by a rise in serotype a.

No clinical features reliably distinguish *H. influenzae* CAP from CAP caused by other pathogens. In a review of more than 9000 patients with CAP enrolled in prospective cohort study in Germany, purulent sputum, receipt of a pneumococcal vaccination, and a history of chronic respiratory comorbidities were the only clinical characteristics significantly more common in patients with *H. influenzae* CAP than in those with CAP from other causes.[167]

Roughly 25% of *H. influenzae* strains produce a β-lactamase.[168] While awaiting susceptibility testing, suggested antibiotic regimens for confirmed moderate or severe *H. influenzae* CAP include second- or third-generation cephalosporins, β-lactam–β-lactamase inhibitor combinations, and respiratory fluroquinolones.

Mycoplasma pneumoniae

Mycoplasmas are the smallest self-replicating free-living organisms. More than 200 *Mycoplasma* species have been identified, of which *M. pneumoniae* is the most relevant to human disease. *M. pneumoniae* does not exist freely in nature but rather is an obligate parasite, residing primarily on the epithelial cell surface of hosts on which it relies for necessary nutrients.[169] Cytoadherence and motility are achieved in part through an elongated attachment organelle.[170] Production of a recently identified virulence factor, the community-acquired respiratory distress syndrome toxin, is an important driver of disease pathogenesis and contributes to the dry cough that characterizes infection.[171] Spread occurs through inhalation of respiratory droplets during close contact.

As the most common bacterial cause of acute uncomplicated bronchitis and a frequently identified pathogen in outpatient CAP, *M. pneumoniae* is an important cause of respiratory infections in the ambulatory care setting.[172] Community outbreaks of *M. pneumoniae* are well described.[170] In hospitalized patients, confirmed infection is less common. As an example, in the CDC EPIC study, only 2% of

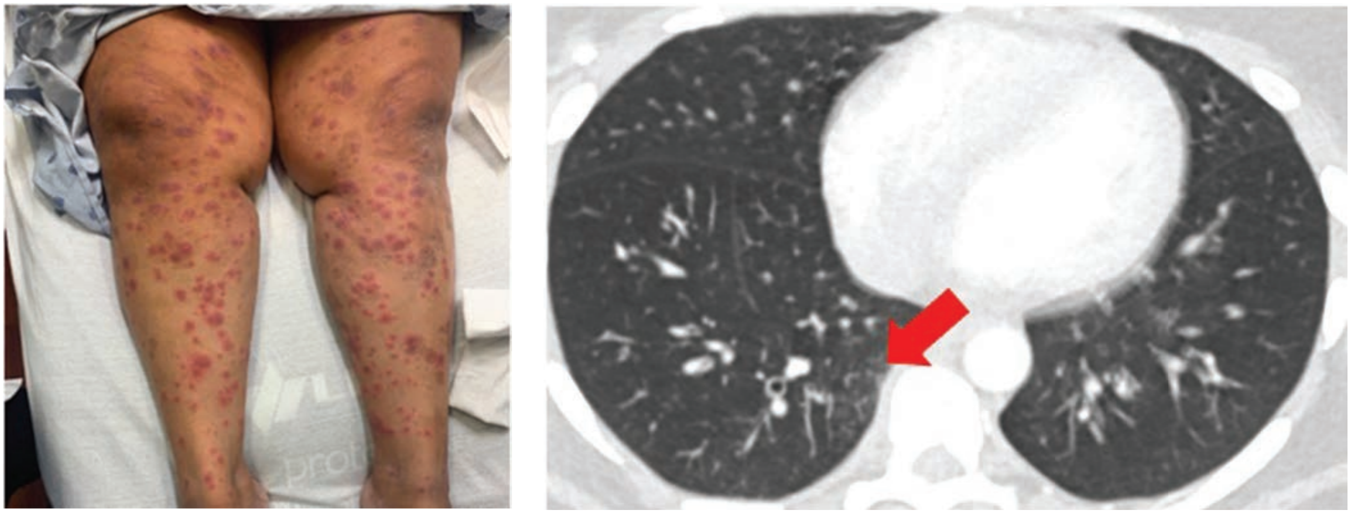

Figure 128-7 **A.** Lower extremities of a patient with community-acquired pneumonia secondary to *Mycoplasma pneumoniae* showing numerous targetoid pink papules with central dusky centers. The patient also had prominent oral and genital mucositis consistent with a diagnosis of *Mycoplasma*-induced rash and mucositis. **B.** Axial chest computed tomography from the same patient showing areas of tree-in-bud opacities and airway wall thickening *(red arrow)*.

patients had documented *M. pneumoniae* infection despite routine use of PCR-based testing of the nasopharynx.

M. pneumoniae CAP is viewed as the quintessential "atypical" pneumonia, associated with more subacute symptoms, a less productive cough, less severe disease, and more subtle radiographic abnormalities than CAP due to *S. pneumoniae*. In a comparison of CT findings between patients with *M. pneumoniae* and *S. pneumoniae* CAP, patients with *M. pneumoniae* were more likely to have bronchial wall thickening, ground-glass opacities, and centrilobular nodules.[173] Despite these broad distinctions between CAP caused by typical and atypical pathogens, there are no validated tools to reliably identify *M. pneumoniae* infection in the absence of diagnostic testing. Interestingly, bacterial co-detections can be found in 35% of *M. pneumoniae* CAP cases, especially in children.[174]

M. pneumoniae lacks a cell wall and is bounded by only a plasma membrane. As a result, it does not reliably take up Gram stain. *M. pneumoniae* is also difficult to isolate in culture, requiring several weeks of incubation with special medium. Given these limitations, PCR-based testing of respiratory samples with nucleic acid amplification is now the standard for diagnosis in acutely ill patients.

M. pneumoniae is unique in its ability to cause extrapulmonary disease including central nervous system disease (e.g., encephalitis, meningitis, and Guillain-Barré syndrome), cold-agglutinin hemolytic anemia, dermatologic disease (e.g., erythema multiform, Stevens-Johnson syndrome), pericarditis, and hepatitis (Fig. 128-7).[175]

Given its lack of a cell wall, *M. pneumoniae* is resistant to β-lactams. Macrolides or respiratory fluoroquinolones are the mainstay of therapy for documented infection. Macrolide resistance is an emerging issue for *M. pneumoniae*, with rates as high as 15% in some locales.

Legionella pneumophila

L. pneumophila is an intracellular, aerobic, faintly Gram-negative bacillus. Of at least 15 serotypes, serotype 1 is responsible for more than 80% of infections in the United States.[176] Infection with *L. pneumophila* causes two distinct syndromes: Pontiac fever, a self-limited nonpneumonic febrile illness, and Legionnaires' disease, a form of CAP named for a 1976 outbreak in Philadelphia (Fig. 128-8).

L. pneumophila is found in freshwater environments, artificial water supplies (e.g., cooling towers and plumbing systems), and moist soil. Infection occurs predominantly through inhalation of aerosolized particles and less commonly though aspiration of contaminated water. Person-to-person transmission is rare but has been recently described.[177] Nosocomial and nursing home outbreaks occur and can be triggered by inadequate cleaning of respiratory equipment.[178] Major risk factors for disease include advanced age, cigarette smoking, chronic lung disease, and immunocompromised states.

L. pneumophila CAP is uncommon, with detection rates of less than 2% in large U.S. studies.[37,66] In a retrospective review of more than 150,000 patients with pneumonia in a large U.S. healthcare network, only 26% were tested for pneumonia with 1.5% testing positive for *L. pneumophila* infection.[66] Compared to patients with negative testing, patients who tested positive for *L. pneumophila* had higher rates of tobacco use (38.0% vs. 22.0%), alcohol abuse (9.2% vs. 5.0%), diarrhea (8.9% vs. 4.1%), and hyponatremia (36% vs. 14%). The predictive value of these associations is unclear, as many patients with these characteristics did not undergo *L. pneumophila* testing.

L. pneumophila is difficult to detect on Gram stain and requires buffered charcoal yeast for growth on culture, making routine analysis of expectorated sputum an unreliable diagnostic test. Urinary antigen testing is the most clinically useful testing method given its rapid turnaround time and appealing test characteristics (a sensitivity of 74% and specificity of 99% in a 2009 meta-analysis).[85] Importantly, urinary antigen testing detects only infection with serogroup 1. While this serogroup is responsible for the vast majority of *Legionella* infections in the United States, human infection has been described with nearly all other serogroups and multiple other *Legionella* species. As an example, *L. longbeachae* is responsible for roughly 30% of infections in Australia and New Zealand.[179] As a result, a negative urinary antigen test does not definitively rule out *Legionella* infection.

The treatment of choice for *Legionella* pneumonia is either azithromycin (500 mg per day) or levofloxacin (750 mg per day). No randomized controlled trials compare these two antibiotics, although observational studies suggest both are effective.[180] No evidence suggests that combination therapy with these two agents or the addition of rifampin improves outcomes.

Duration of therapy for confirmed *L. pneumophila* pneumonia is unclear. For immunocompetent patients, discontinuation of therapy

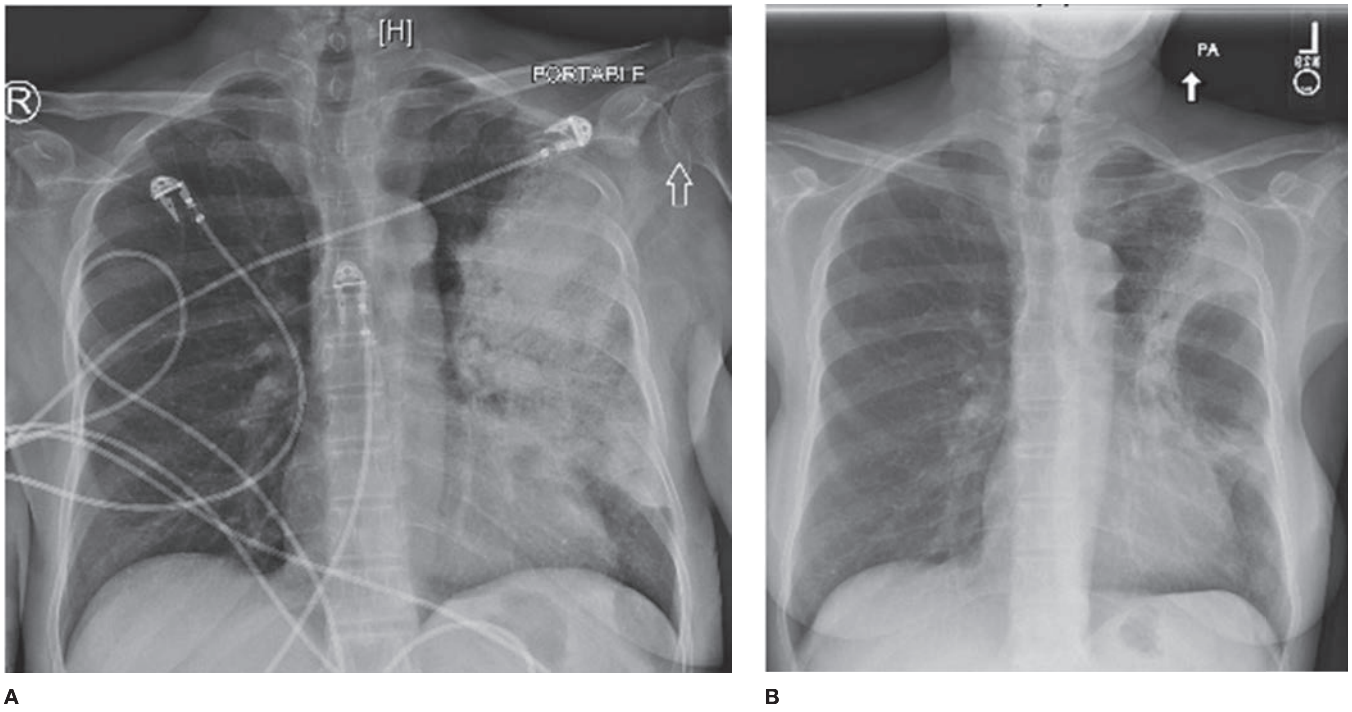

Figure 128-8 **A**. Portable chest radiograph showing dense left-sided opacities in an immunocompromised patient with community-acquired pneumonia secondary to *Legionella pneumophila* serotype 1. **B**. Posteroanterior chest radiograph performed 3 months after hospital discharge showing coalescing curvilinear opacities in the left lung.

guided by objective measures of clinical stability after a minimum of 5 days of antibiotics is reasonable. Immunocompromised patients, especially those with severe disease, may benefit from a more prolonged treatment course.

CHAPTER 129

Nosocomial Pneumonia, Including Ventilator-associated Pneumonia

Andrew T. Roth
Marin H. Kollef

INTRODUCTION

Hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP) are the most frequent causes of healthcare-associated infections (HAIs) and represent significant clinical and economic burdens on healthcare systems. Definitions for each of these conditions are provided in Table 129-1. HAP and VAP are frequently associated with multidrug-resistant (MDR) microorganisms, leading to further morbidity and mortality in hospitalized patients. VAP is considered a device-associated HAI and is, therefore, reported to the National Healthcare Safety Network (NHSN), the surveillance branch of the Centers for Disease Control and Prevention (CDC). According to the latest published data from the NHSN, 10,037 cases of VAP were reported from 2015 to 2017.[1] This chapter focuses on the epidemiology of infection, the microorganisms responsible for infection, the complexities surrounding the diagnosis, and the preventive and therapeutic management strategies used to combat nosocomial pneumonia.

EPIDEMIOLOGY

HAP and VAP account for approximately 28% of HAIs and are collectively the most frequent cause of nosocomial infection.[2,3] Epidemiologic data estimate an overall prevalence of nosocomial pneumonia in hospitalized patients of 0.89%, with the burden substantially higher among patients in the intensive care unit (ICU).[2,3] While the majority of cases of nosocomial pneumonia occur in nonintubated patients, mechanical ventilation is the most important risk factor for pneumonia, increasing the incidence up to 20-fold.[2,4,5] Approximately 10% of patients undergoing mechanical ventilation develop VAP.[6] In a 1-day point prevalence study involving ICU patients from centers in 88 different countries, investigators found respiratory tract infections were the most common infection in the ICU, accounting for 60.1% of infections. Furthermore, respiratory tract infections were the most frequent reason for antibiotic prescription in the ICU. Overall, greater than 50% of the infections documented in this study were categorized as hospital-acquired or healthcare-associated, rather than community-acquired.[3] A multicenter, prospective cohort analysis conducted in Canada demonstrated a VAP rate of 14.8 cases per 1000 ventilator days, with half occurring on or before day 7. While the cumulative risk for developing VAP increased with duration of ICU stay, the daily risk increased until day 5 and then subsequently decreased.[7]

TABLE 129-1 Definitions of Nosocomial Pneumonia[a]

Pneumonia Category	Definition
HAP, hospital-acquired pneumonia	Pneumonia diagnosed 48 h or more after hospital admission Can occur in nonventilated or ventilated patients
VAP, ventilator-associated pneumonia	Pneumonia diagnosed 48 h or more after endotracheal intubation

[a] *Clinical criteria for pneumonia include new or progressive lung infiltrate and at least two of the following: hyperthermia or hypothermia, elevated white blood cell count, purulent tracheal secretions or sputum, and worsening oxygenation.*

Determining the economic impact of VAP and the associated morbidity and mortality is challenging. Critically ill patients have multiple, evolving, complex disease processes that make it difficult to isolate VAP as the sole cause of excess cost, morbidity, or death. Multiple studies have been performed with variable findings. In a recent, large, international study, patients with respiratory tract infections had an ICU mortality rate of 24.8% and an in-hospital mortality rate of 31.9%.[3] An older case-control analysis revealed a crude mortality of 54%, an attributable mortality of 27%, and a 13-day increase in ICU length of stay compared with matched controls.[8] A larger, case-matched, prospective cohort study demonstrated an attributable ICU length of stay of 4 days and an attributable mortality of 6%.[9] A retrospective, matched cohort study using a large U.S. database estimated an increase of >$40,000 in mean hospital charges per patient.[10] In addition, a more recent retrospective, matched cohort study using ICD-9 coding to identify VAP revealed mean hospitalization costs of $99,598, which was $39,828 greater than those patients without VAP.[11]

Recent advances in statistical methodology allow for the control of the effect that severity of illness can have on the attributable mortality associated with VAP, not only at the time of infection but over the course of a hospitalization during disease evolution. Employing a statistical technique from the field of causal inference, an analysis of a large French national database resulted in a lower estimation of attributable mortality associated with VAP of 1% on day 30 and 1.5% on day 60.[12] Modifiable factors, particularly the timely initiation of appropriate antibiotics, certainly affect the aforementioned estimates. Although debate continues over the attributable mortality and cost of VAP, the condition undoubtedly imposes significant clinical and economic burdens.

Multiple databases track HAIs in the United States, including HAP and VAP. The NHSN functions as the CDC's surveillance system for HAIs and collects data from more than 5000 participating healthcare facilities. The NHSN Device-Associated Module includes data from patients undergoing mechanical ventilation. Analysis of data in 2012 categorized rates of VAP based on ICU location, with the highest incidence in burn, neurologic, neurosurgical, and surgical ICUs, ranging from 2.1 to 4.4 cases per 1000 ventilator days.[13] VAP was diagnosed less frequently in medical and medical/surgical ICUs, occurring at a rate of 0.9 to 1.0 cases per 1000 ventilator days (Table 129-2).[13] Compared to its report using data from 2006, the results demonstrated an overall decrease in the rate of VAP.[14] However, it is unclear whether the incidence of VAP is truly decreasing, or whether the NHSN definition of VAP is being more rigorously applied over time.[15]

The Medicare Patient Safety Monitoring System (MPSMS) has independently collected data on VAP within the Medicare population since 2005. Independent audit of these data showed stable rates of VAP at approximately 10% of mechanically ventilated patients from 2005 to 2013, in contrast with NHSN data.[6] Additionally, analysis of survey data from the CDC's Emerging Infections Program showed that despite an overall decrease in the number of HAIs, the rate of VAP was not significantly changed when comparing data from 2011 and 2015.[2] Given that the CDC/NHSN pneumonia

TABLE 129-2 2012 National Healthcare Safety Network VAP Rates Based on ICU Location in Major Teaching Hospitals

ICU Location	VAP Cases	Ventilator Days	Rate[a]
Burn	86	19,503	4.4
Medical	396	419,123	0.9
Medical/surgical	1398	1,330,178	1.0
Neurologic	62	20,859	3.0
Neurosurgical	210	98,026	2.1
Surgical	472	223,639	2.1
Cardiothoracic	319	190,785	1.7
Trauma	508	141,314	3.6

[a] Expressed as number of VAP cases per 1000 ventilator days.

Data from Dudeck MA, Weiner LM, Allen-Bridson K, et al. National Healthcare Safety Network (NHSN) report, data summary for 2012, Device-associated module. Am J Infect Control. 2013;41(12):1148–1166.

definitions (Table 129-3) were thought to lack accuracy, objectivity, and consistency, a new surveillance algorithm was introduced to identify ventilator-associated events (VAEs) in January 2013.[1] The goal of the new algorithm is to identify complications of mechanical ventilation including, but not limited to, VAP by using objective changes in ventilator parameters indicative of worsening oxygenation (Fig. 129-1).

MICROBIOLOGY

The etiologies of HAP and VAP depend on multiple factors, including co-existing diseases, geography, ICU population, duration of mechanical ventilation, previous antibiotic therapy, and the method used to obtain respiratory cultures. More microbiologic data are available for VAP compared with HAP, as VAP is a reportable condition and microbiologic samples of the lower respiratory tract can be easily obtained.

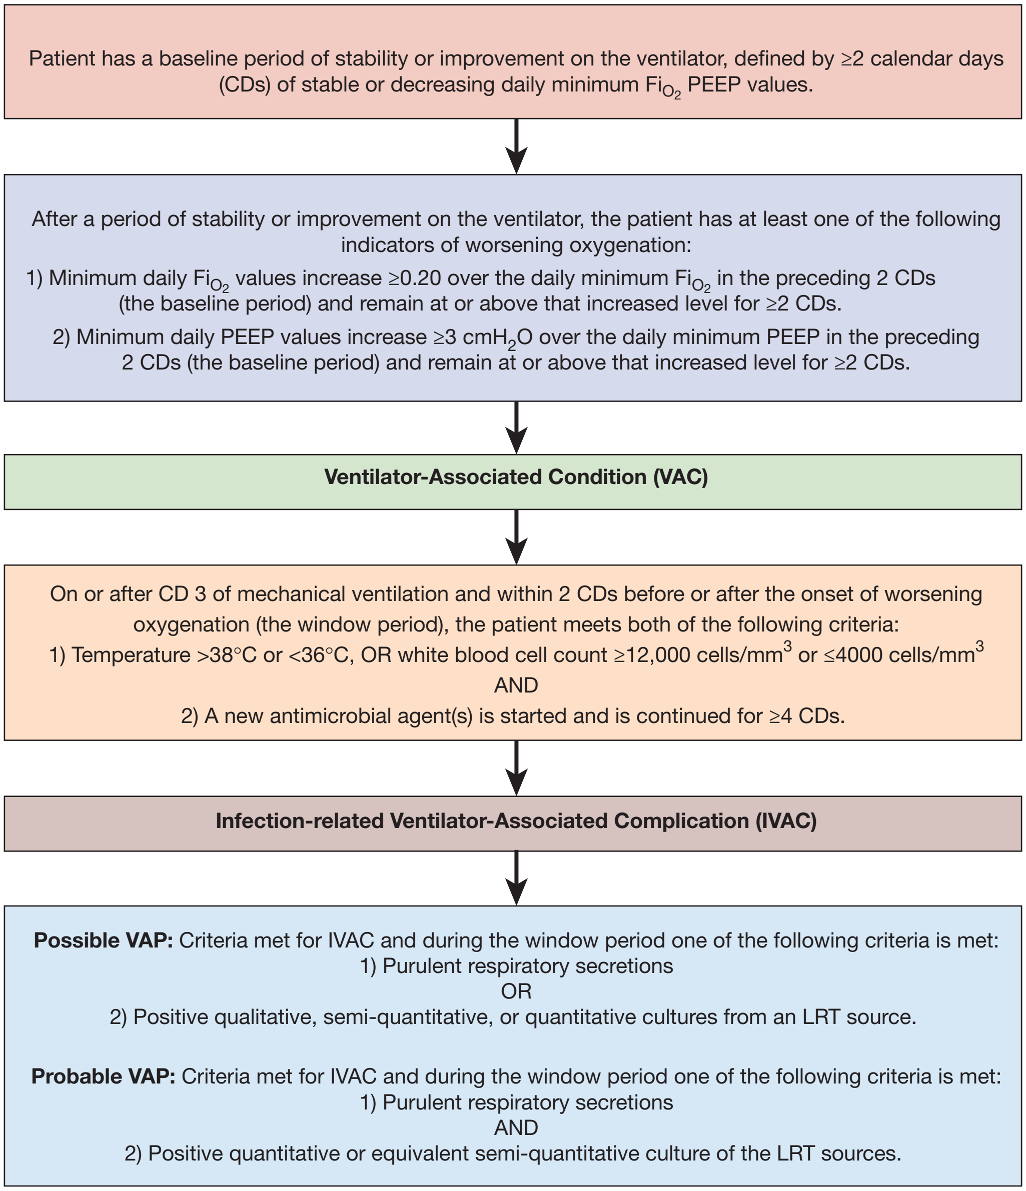
The most recent analysis of NHSN data examined microbiologic data from 9266 cases of VAP across ICUs in the USA from 2015 to 2017.[1] While Gram-negative bacilli (GNB) made up the majority of organisms, *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), was the most common pathogen, accounting for 28.8% of organisms. *Pseudomonas aeruginosa* made up 12.9%. The Enterobacteriaceae collectively accounted for 26.7% of organisms, including *Klebsiella* spp. (10.1%), *Enterobacter* spp. (8.4%), *Escherichia coli* (5.6%), *Proteus* spp. (1.4%), and *Citrobacter* spp. (1.2%). Etiologic organisms of community-acquired pneumonia (CAP) were a less frequent but significant cause of VAP, particularly *Haemophilus influenzae* (5.9%). Important GNB infections with special resistance patterns included *Stenotrophomonas maltophilia* (4.0%), *Acinetobacter* spp. (3.2%), and *Burkholderia cepacia* (0.3%) (Table 129-4).

Similar microbiologic data were seen in the 2020 Prospective Identification of Pneumonia in Hospitalized Patients in the Intensive Care Unit (PROPHETIC) study, which prospectively identified and followed hospitalized patients in the United States at high risk for developing HAP/VAP. Among the patients who developed VAP and grew bacteria on respiratory culture, *S. aureus*, including MRSA, was the most common organism, accounting for 23.5% of cases followed by *P. aeruginosa* (11.5%), *Klebsiella* spp. (10.6%), *Enterobacter* spp. (7.0%), *E. coli* (6.2%), *Stenotrophomonas maltophilia* (3.9%), *H. influenzae* (3.6%), *Acinetobacter* spp. (3.1%), and *Serratia* spp. (2.2%). No bacterial pathogens were isolated on culture in 34.2% of cases.[16]

TABLE 129-3 Centers for Disease Control and Prevention National Healthcare Safety Network Pneumonia Definitions

PNEU Type	Definition
PNU1	Two or more serial chest radiographs with at least ***one*** of the following: new or progressive and persistent infiltrate, consolidation, or cavitation and At least ***one*** of the following: • Fever (>38°C) • Leukopenia (<4000 WBC/mm^3) or leukocytosis (≥12,000 WBC/mm^3) • Altered mental status in an adult ≥70 years of age without an alternative etiology and At least ***two*** of the following: • New onset of purulent sputum or change in character of sputum or increased secretions/suction requirements • New-onset or worsening cough, dyspnea, or tachypnea • Rales or bronchial breath sounds • Worsening gas exchange
PNU2	Two or more serial chest radiographs with at least ***one*** of the following: new or progressive and persistent infiltrate, consolidation, or cavitation At least ***one*** of the following: • Fever (>38°C) • Leukopenia (<4000 WBC/mm^3) or leukocytosis (≥12000 WBC/mm^3) • Altered mental status in an adult ≥70 years of age without an alternative etiology and At least ***one*** of the following: • New onset of purulent sputum or change in character of sputum or increased secretions/suction requirements • New-onset or worsening cough, dyspnea, or tachypnea • Rales or bronchial breath sounds • Worsening gas exchange and At least ***one*** of the following: • Positive blood culture not related to another source of infection • Positive pleural fluid culture • Positive quantitative culture from minimally contaminated LRT specimen • ≥5% of BAL cells containing intracellular bacteria • Histopathologic examination revealing ***one*** of the following: abscess formation, positive quantitative culture, or invasion of lung parenchyma by fungal hyphae or pseudohyphae

PNU3 is a separate definition applied to immunosuppressed patients. Definitions can be found at www.cdc.gov/nhsn.



Patient has a baseline period of stability or improvement on the ventilator, defined by ≥2 calendar days (CDs) of stable or decreasing daily minimum Fi_{O_2} PEEP values.

After a period of stability or improvement on the ventilator, the patient has at least one of the following indicators of worsening oxygenation:

1) Minimum daily Fi_{O_2} values increase ≥0.20 over the daily minimum Fi_{O_2} in the preceding 2 CDs (the baseline period) and remain at or above that increased level for ≥2 CDs.

2) Minimum daily PEEP values increase ≥3 cmH_2O over the daily minimum PEEP in the preceding 2 CDs (the baseline period) and remain at or above that increased level for ≥2 CDs.

Ventilator-Associated Condition (VAC)

On or after CD 3 of mechanical ventilation and within 2 CDs before or after the onset of worsening oxygenation (the window period), the patient meets both of the following criteria:

1) Temperature >38°C or <36°C, OR white blood cell count ≥12,000 cells/mm^3 or ≤4000 cells/mm^3

AND

2) A new antimicrobial agent(s) is started and is continued for ≥4 CDs.

Infection-related Ventilator-Associated Complication (IVAC)

Possible VAP: Criteria met for IVAC and during the window period one of the following criteria is met:

1) Purulent respiratory secretions

OR

2) Positive qualitative, semi-quantitative, or quantitative cultures from an LRT source.

Probable VAP: Criteria met for IVAC and during the window period one of the following criteria is met:

1) Purulent respiratory secretions

AND

2) Positive quantitative or equivalent semi-quantitative culture of the LRT sources.

Figure 129-1 Abbreviated NHSN surveillance algorithm for ventilator-associated events.

Even with special attention to collection method and culture media, anaerobic bacteria do not appear to be important causes of nosocomial pneumonia outside of special circumstances, such as lung abscess or empyema. In a prospective study of 185 episodes of VAP, invasive samples were collected using a protected specimen brush and cultured in anaerobic media, yielding growth of *Veillonella parvula* in a single case.[17] Cases of *Legionella* species are uncommon causes of nosocomial pneumonia but have been reported in the context of contaminated water supply.[18] Viral infections are important and underappreciated causes of respiratory failure in the ICU and frequently require mechanical ventilation.[19] Transmission of nosocomial viral infections including influenza virus and rhinovirus has been documented.[20,21]

Antimicrobial resistance remains a critical issue in management of nosocomial pneumonia, particularly with infection due to *S. aureus* and *P. aeruginosa*. Infection with MDR microorganisms is associated with increased mortality, in part due to delayed time to appropriate antimicrobial therapy.[3] NHSN data from 2015 to 2017 showed that 36.9% of tested *S. aureus* isolates were methicillin-resistant.[1] Analysis of *P. aeruginosa* isolates from the same NHSN data showed that resistance was common across different antibiotic classes, with 16.8% of isolates showing resistance to at least one agent in three different antibiotic classes.[1] There is significant variation in the microbiologic etiology of HAP and VAP between different hospitals[22] and between different parts of a given hospital.[23] Therefore, optimal management requires knowledge of local antibiogram data and appropriate tailoring of antimicrobial therapy.

PATHOPHYSIOLOGY

Nosocomial pneumonia usually occurs through the aspiration of microorganisms colonizing the aerodigestive tract in a host with altered immunity, while direct inhalation and hematogenous dissemination of bacteria are less frequent routes of infection. Hospitalized patients are at increased risk for oropharyngeal colonization with pathogenic microorganisms due to pharmacologic and dietary alterations in gastric pH, exposure to contaminated respiratory equipment and hospital water systems, transmission of bacteria via healthcare workers, and spread of microorganisms through respiratory droplets.

Aspiration during sleep occurs in a large number of normal subjects, but the volume aspirated is small and, more importantly, the pathogenicity of the microorganisms is minimal. Hospitalized

TABLE 129-4 Distribution and Rank of 9622 Isolated Pathogens Associated with VAP in Hospital ICUs Reported to the National Healthcare Safety Network Between 2015 and 2017

Pathogen	Number of Isolates (%)	Rank

Data from Weiner-Lastinger LM, Abner S, Edwards JR, et al. Antimicrobial-resistant pathogens associated with adult healthcare-associated infections: Summary of data reported to the National Healthcare Safety Network, 2015-2017. Infect Control Hosp Epidemiol. 2020;41(1):1–18.

patients are considered more likely to aspirate larger volumes of virulent bacteria with greater frequency due to decreased sensorium, impaired cough mechanism, difficulty swallowing, and impaired gut motility.[24] The role of colonization of the upper respiratory and digestive tracts is well studied. Prospectively collected culture data showed that 23% of patients admitted to a medical ICU who were colonized with GNB developed a nosocomial respiratory infection compared with only 3% of noncolonized patients.[25] A more recent study utilizing genomic analysis demonstrated that strains of bacteria isolated from the lower respiratory tract (LRT) in cases of nosocomial pneumonia were identical to those strains colonizing the oropharynx and/or stomach.[26]

Alterations in gastric pH promote growth of bacteria in a normally sterile environment, increasing the risk for nosocomial pneumonia.[27–29] Critically ill patients requiring mechanical ventilation are at increased risk for developing stress ulcers and, thus, are often treated with histamine type 2 (H_2) antagonists and proton pump inhibitors for prevention.[30] While these strategies provide effective prophylaxis, use of H_2 antagonists and proton pump inhibitors is associated with increased rates of gastric colonization and pneumonia, including VAP, and therefore should only be used when there is significant risk of developing stress ulcers.[31,32] Furthermore, recent meta-analysis showed that in patients receiving enteral tube feeds, the use of H_2 antagonists was associated with increased frequency of HAP without reduction in the frequency of gastrointestinal bleeding.[29]

An endotracheal tube serves as a reservoir for bacteria from the upper airway to leak around the cuff and gain entry into the LRT. Manufacturers have developed novel endotracheal tubes with antimicrobial properties that prevent biofilm formation.[33] Humidifiers and nebulizers may be infected, thereby allowing for the transfer of microorganisms between patients by respiratory personnel. Contaminated water supply systems have led to previous nosocomial outbreaks of *Legionella* species.[18] Fungal infections have resulted from hospital renovations and construction, contaminated air supply, and poor filtration.[34]

VAP caused by MDR microorganisms is a well understood example of how alterations in the host microbiome contribute to the development and progression of nosocomial pneumonia and other infections.[35] It is increasingly apparent that microbial imbalances within the body, such as an impaired intestinal microbiome, represent important pathogenic mechanisms for the development of nosocomial lung infections. Investigators have demonstrated that critically ill subjects have lower initial diversity of their microbiota in both the upper and lower respiratory tract compared to healthy controls.[36] The presence of endotracheal tubes and antibiotic administration may promote pathogenic bacterial colonization in the airways, contributing to both lower microbiota diversity and the development of an intermediate respiratory infection termed ventilator-associated tracheobronchitis (VAT).[37]

VAT represents a compartmentalized host response associated with a better overall prognosis compared with VAP.[38,39] If the aforementioned response is not compartmentalized, progression to VAP is likely, and other organ failures, including the acute respiratory distress syndrome (ARDS), may occur. In one study, examination of the lungs of critically ill patients revealed a correlation between lung-specific microbiota and clinical outcomes.[40] Patients with increased lung bacterial burden had fewer ventilator-free days. Moreover, the investigators found that the community composition of lung bacteria, driven primarily by gut-associated bacteria, was also predictive of ventilator-free days and the presence of ARDS. Thus, both bacterial burden and community composition of the microbiota influence disease presentation and clinical outcomes, including the occurrence of nosocomial pneumonia.

The early, hyperinflammatory response that occurs in trauma and sepsis may cause multisystem organ failure and death. Improvements in the management of sepsis have decreased rates of early death, and patients now often succumb to protracted or nosocomial infections. Recent evidence suggests that a subset of patients who survive the cytokine storm associated with the proinflammatory response of sepsis develop an immunodeficient state promoting viral reactivation and nosocomial infection, including pneumonia. Immunomodulatory therapies to attempt to obviate this risk are currently being investigated.[27]

RISK FACTORS

Given the important pathophysiologic roles of aspiration and colonization of the aerodigestive tract, it is logical that the significant risk factors for nosocomial pneumonia involve these processes. A complete list of risk factors is provided in Table 129-5.

Mechanical ventilation is the single most important risk factor for nosocomial pneumonia, increasing the risk up to 20-fold.[2,4,5] Reintubation is associated with further increased risk of developing VAP.[41] Severity and type of disease are known risk factors for nosocomial pneumonia. An Apache II score of at least 16 and an organ system failure index of 3 or greater have both been linked to VAP.[5,42] Nosocomial pneumonia occurs more frequently in postsurgical patients, particularly burn and trauma victims.[43] The incidence is also higher in COPD likely due to greater colonization rates, impairment of airway clearance, and risk of ARDS as a result of prolonged mechanical ventilation.[44–46]

Aspiration occurs more frequently in the supine position and may be exacerbated by the presence of a nasogastric tube combined with early enteral nutrition.[47–50] As previously mentioned, aspiration is more frequent and the risk of macroaspiration is increased in

TABLE 129-5 Risk Factors for Nosocomial Pneumonia Determined by Regression Analysis

Aspiration	Colonization	Aspiration/Colonization	Other
Documented aspiration risk	Frequent ventilator circuit changes	Mechanical ventilation	Severity of illness (Apache, SOFA)
Supine position	Prior antibiotic use	Reintubation	ARDS
Nasogastric tube	COPD	Admission diagnosis of trauma or cerebrovascular accident	Age >60
Enteral nutrition			Transport out of ICU
Decreased endotracheal tube cuff pressure			PRBC transfusion
Neuromuscular disease			
Coma/head trauma

Data from Cook DJ, Kollef MH. Risk factors for ICU-acquired pneumonia. JAMA. 1998;279(20):1605–16056; Bergin SP, Coles A, Calvert SB, et al. PROPHETIC: Prospective Identification of Pneumonia in Hospitalized Patients in the ICU. Chest. 2020;158(6):2370–2380.

hospitalized patients.[24] Postpyloric feeding may reduce gastroesophageal reflux, but the impact on VAP incidence is unclear. Antacids and H_2 antagonists used for stress ulcer prophylaxis are independent risk factors for nosocomial pneumonia, as alterations in gastric pH promote bacterial colonization.[51,52] In addition, prior antibiotic administration may select for infection by MDR microorganisms.[16,42]

Work is currently underway to identify patients at highest risk for nosocomial pneumonia in order to optimize its prevention, diagnosis, and treatment. The PROPHETIC study prospectively identified patients at high risk for nosocomial pneumonia based on need for supplemental oxygen or ventilatory support, followed them over time for development of infection, and then developed a multivariable logistic model in order to identify risk factors, comorbidities, and exposures associated with pneumonia. The study found increased odds of developing nosocomial pneumonia in patients receiving enteral nutrition, with documented aspiration risk, with admission diagnosis of trauma or cerebrovascular accident, and with receipt of antibiotics in the previous 90 days.[16]

In patients with CAP, determining which patients are at highest risk for infection due to MDR microorganisms is an area of active investigation. Rapid identification of these patients is important because delay in appropriate antimicrobial therapy is associated with increased morbidity and mortality.[53] Healthcare-associated pneumonia (HCAP), an entity defined in the 2004 ATS/IDSA guidelines on nosocomial pneumonia, includes a large group of patients with exposures, including treatment at outpatient dialysis and wound care centers, recent hospitalization, and recent receipt of IV antibiotics or chemotherapy, in an effort to capture patients from the community with increased risk for pneumonia due to MDR microorganisms.[54] In a review of hospital admissions for pneumonia in New York City, patients meeting criteria for HCAP had a mortality rate of 15.6% compared with 7.9% in patients with CAP.[55] Several observational studies support HCAP as an effective set of criteria to identify those with pneumonia in the community at high risk for infection due to MDR microorganisms.[56,57] However, recent prospective studies have raised doubt about whether HCAP is an effective way to identify those most at risk for infection due to MDR microorganisms and suggested that they may result in overuse of broad-spectrum antibiotics.[58,59]

Particular attention has been paid to three bacteria which make up a large share of the MDR microorganisms in CAP and result in excess mortality: *P. aeruginosa*, β-lactamase–positive Enterobacteriaceae, and MRSA (PES).[60] In order to identify at-risk patients, the PES Score was generated from analysis of an observational prospective study of patients admitted to the hospital with diagnosis of pneumonia and includes the patient's age, sex, antibiotic use, medical comorbidities, and level of consciousness on admission.[53] The inclusion of antibiotic history is further supported by the PROPHETIC study, which prospectively identified receipt of antibiotics in the previous 90 days as a risk factor for pneumonia due to MDR microorganisms. Multivariable logistic regression analysis of a large cohort of immunocompromised patients presenting to the hospital with CAP identified several factors with increased odds of *P. aeruginosa* pneumonia, including severe COPD, tracheostomy, inhaled corticosteroid use, indwelling catheter (vascular or urinary), and prior history of *P. aeruginosa* infection.[61]

VAP was previously classified as early-onset or late-onset based on data that showed significantly increased risk of infection with MDR microorganisms in patients with a diagnosis of VAP after greater than 7 days of mechanical ventilation.[62] While early-onset VAP was previously thought to confer a better prognosis due to decreased risk of infection with MDR microorganisms, more recent data have challenged this. In a retrospective review comparing VAP diagnosed before or after 5 days of initiation of mechanical ventilation, no difference was found in the incidence of MDR microorganisms.[63] A prospective observational trial also concluded that duration of mechanical ventilation alone was not predictive of risk of VAP due to MDR microorganisms.[64] Rather, assessment of risk factors, including recent antibiotic usage and local prevalence of MDR microorganisms, is needed to properly strategize treatment in patients with early-onset VAP.[65]

DIAGNOSIS

The diagnosis of nosocomial pneumonia remains challenging. Optimal use of both clinical and microbiologic data is needed to maximize diagnostic accuracy. Nosocomial pneumonia should be suspected in any patient with new or progressive radiographic opacities and clinical signs or symptoms indicative of infection, including fever, leukocytosis or leukopenia, purulent sputum, or worsening oxygenation. These clinical findings are neither sensitive nor specific, and there is no gold standard for the diagnosis of HAP or VAP; even postmortem histologic examination does not provide 100% specificity.[66] Microbiologic data can also be difficult to interpret, as false-positive and false-negative results are common.

The clinical strategy employs the previously mentioned clinical and radiographic criteria in diagnosing nosocomial pneumonia. A prospectively specified combination of two out of three clinical criteria (leukocytosis, purulent secretions, and fever) and a radiographic infiltrate yielded a sensitivity of 69% and a specificity of 75% for the diagnosis of VAP in 25 mechanically ventilated patients using histology and quantitative lung tissue culture on autopsy as the reference. Increasing the number of clinical criteria resulted in greater specificity but at the cost of lesser sensitivity.[67] However, in a postmortem analysis of 39 mechanically ventilated patients, clinical criteria did not provide a reliable positive predictive value for histologic pneumonia.[66]

The bacteriologic strategy uses quantitative cultures of the LRT via endotracheal aspirate, protected specimen brush, or bronchoalveolar lavage (BAL) to confirm or eliminate the diagnosis of nosocomial pneumonia based on thresholds of bacterial growth. These thresholds differ depending on the method of respiratory sampling and are as follows: $\geq 10^5$ colony-forming units (CFU)/mL for an endotracheal aspirate, $\geq 10^4$ CFU/mL for a BAL, and $\geq 10^3$ CFU/mL for a protected specimen brush. Results of these procedures guide decisions such as when to initiate or stop antibiotics and the drug(s) to be used against the offending agent. There are no definitive data to support the use of one sampling technique over another; however, cellular analysis of BAL fluid may provide an advantage, as a sample containing $<50\%$ neutrophils produced excellent negative predictive value in one study.[66] Also, given the multifocal nature of VAP, even mini-BAL samples obtained blindly without the use of bronchoscopy may be effective.[68–70]

A semiquantitative endotracheal aspirate culture can be used to identify a pathogen and, if positive, has been shown to correlate with quantitative cultures of the LRT obtained via protected specimen brush.[71] Also, a negative endotracheal aspirate culture has high sensitivity and good negative predictive value if antibiotics have not recently been changed.[72] However, semiquantitative cultures are not as reliable as quantitative cultures of the LRT due to an inability to differentiate between colonization and infection.

The use of clinical criteria and a reliance on semiquantitative cultures can be overly sensitive, resulting in unnecessary antibiotic use and potential delay in the identification of extrapulmonary infection. The bacteriologic strategy has resulted in less and more narrowed antibiotic use, an important point given the surge of MDR microorganisms in the ICU setting.[73–75] A major disadvantage with this approach is the concern for false negatives, which could result in cases of nosocomial pneumonia going untreated, especially in the setting of recently introduced antibiotics.[76] A recent pilot study utilized metagenomic shotgun sequencing in BAL fluid as a novel tool to identify bacterial pathogens in a highly sensitive manner, which may represent a promising future approach.[77]

Multiple studies have compared the clinical and bacteriologic strategies. Only one prospective, randomized trial demonstrated a mortality benefit at 14 days when using the bacteriologic strategy.[73] Others have failed to reproduce these findings, including a large study conducted by the Canadian Critical Care Trials Group, as well as a comprehensive meta-analysis.[78,79] In addition, the bacteriologic strategy does not seem to reduce the duration of mechanical ventilation or ICU length of stay. Ultimately, the decision to employ either strategy rests with the clinician on a case-by-case basis. If bronchoscopic sampling can be performed safely and the appropriate personnel are available, it is reasonable to utilize this approach as antibiotic decisions may change based on culture results. If the clinical strategy is used, the clinician should reevaluate the patient often for guidance on antibiotic usage. Regardless of the diagnostic strategy, an unstable patient with a high pretest probability of nosocomial pneumonia should be initiated on empiric antibiotics, as a delay in antibiotic administration leads to higher mortality.[80–85]

PREVENTION

Prevention of nosocomial pneumonia centers on minimizing mechanical ventilation and reducing aspiration and bacterial colonization. As mentioned previously, mechanical ventilation is the most important risk factor for nosocomial pneumonia.[2,4,5] Therefore, avoiding intubation and reintubation, shortening the duration of mechanical ventilation, and employing noninvasive methods to improve oxygenation and ventilation when indicated can prevent pneumonia.[41,86,87]

Multiple methods designed to reduce bacterial colonization of the aerodigestive tract have been evaluated for their impact on VAP incidence. In selective decontamination of the digestive tract, nonabsorbable antimicrobial agents are administered directly to the oropharynx and stomach to prevent colonization with GNB and *S. aureus*. While this approach has been shown to have a beneficial effect on nosocomial infection rates and even survival, potential negative effects include cost and selection for antibiotic-resistant microorganisms when utilized in ICUs with high rates of endemic antibiotic resistance.[88–91] Alternatively, selective oropharyngeal decontamination with nonabsorbable antibiotics or chlorhexidine offers a more limited approach. While this has been associated with lower VAP rates in some trials, particularly in cardiac surgery patients, meta-analysis has failed to show clear association with VAP rates in mechanically ventilated patients.[91–93] Furthermore, selective oropharyngeal decontamination with chlorhexidine has been associated with increased mortality in retrospective analyses, including a recent multicenter study, and should be used with caution.[65,94,95] While systemic antibiotics given once at the time of intubation may reduce early-onset VAP, the routine use of prolonged prophylactic, systemic antibiotics cannot be recommended.[96–98] Probiotics may reduce VAP rates; however, no studies performed to date demonstrate a survival benefit.[99,100]

Strategies to reduce aspiration also have been studied. Patients should be managed in a semirecumbent position rather than supine, particularly when receiving enteral nutrition.[101] In a meta-analysis of patients undergoing mechanical ventilation, semirecumbent positioning with the head of the bed elevated to 30 to 60 degrees reduced the frequency of clinically suspected VAP when compared with patients positioned supine.[102] Continuous drainage of subglottic secretions with specialized endotracheal tubes decreases the frequency of VAP but has not been shown to improve mortality or duration of mechanical ventilation.[103] A randomized controlled trial from 2013 showed that monitoring of gastric residual volume was a poor predictor of aspiration and did not change the frequency of VAP.[104] While postpyloric feeding may reduce aspiration, its effect on infection rates and mortality is unknown. In addition, there is no evidence favoring a specific time point for the initiation of enteral feeding.[105]

Several important trials have evaluated changes to the endotracheal tube and ventilator circuit. Silver-coated endotracheal tubes reduce the frequency of VAP, but they have not been shown to reduce mortality and are more costly when compared to standard endotracheal tubes.[33,106] An updated 2017 Cochrane review did not find a difference in mortality or frequency of VAP when comparing use of heat–moisture exchangers or heated humidifiers in mechanically ventilated adults.[107] There is no evidence that frequent changes of the ventilator circuit or early tracheostomies reduce the rate of VAP.[108–110]

Several bundles of prevention measures exist to improve the care of mechanically ventilated patients. The nonprofit Institute for Healthcare Improvement (Boston, USA) developed a programmatic bundle used by many healthcare institutions in the United States, including semirecumbent positioning with the head of the bed elevated at 45 degrees, daily sedation holidays coupled with an assessment of readiness to extubate, and daily oral care with chlorhexidine.[111]

A similar bundling strategy developed by French investigators was evaluated prospectively in a single medical ICU. Components of the bundle included hand hygiene, semirecumbent positioning, maintenance of tracheal cuff pressure, avoidance of gastric overdistention, good oral hygiene, and minimization of tracheal suction. After an initial educational program for healthcare personnel, compliance with each component increased throughout the 24-month study.[112] In a companion evaluation, total VAP rates decreased from 22.6 to 13.1 per 1000 ventilator days after implementation of the bundle.[113]

A multicenter, prospective surveillance trial of 181 ICUs in Spain used a similar strategy and demonstrated a reduction in the frequency of VAP by approximately 50%, which was sustained at 21 months.[114]

A recent meta-analysis of similar preventive bundles in the pediatric population similarly showed reduction in the frequency of VAP.[115]

Thus, the bundling strategy appears to reduce VAP rates and could potentially produce a more substantial impact with improved compliance. Table 129-6 contains a list of recommended prevention strategies.

TABLE 129-6 Strategies for the Prevention of Nosocomial Pneumonia

Recommended	Evidence Level
Shortening the duration of mechanical ventilation	1
Short-course antibiotic therapy (when clinically applicable)	1
Use of noninvasive mask ventilation	1
Oral chlorhexidine	1
Orotracheal intubation preferred for airways	1
Use of heat–moisture exchanger	1
Semierect positioning	1
Polyurethane endotracheal tube cuff	1
Subglottic secretion drainage	1
Silver-coated endotracheal tube	1
Rotational beds	1
Closed endotracheal suctioning	1
Use of protocols/bundles incorporating multiple prevention elements	2
Adequate intensive care unit staffing	2
Avoid reintubation	2
Avoid patient transports	2
Restricted (conservative) blood transfusion	2
Orogastric intubation preferred for feeding tubes	2
***Not* Recommended**	
Routine ventilator circuit changes	1
Chest physiotherapy	1
Early tracheostomy	1
Specific stress ulcer prophylaxis regimen	1
Topical iseganan	1
Oro-digestive decontamination[b] (Topical/topical plus intravenous antibiotics)	1
Aerosolized antibiotics[b]	1
Intravenous antibiotics[b]	1
Routine antibiotic cycling/rotation/heterogeneity[a]	2

Evidence levels: 1, supported by randomized trials; 2, supported by prospective or retrospective cohort studies.

VAP, ventilator-associated pneumonia.

Clin Infect Dis. 2019;68(9): 1482–1493.

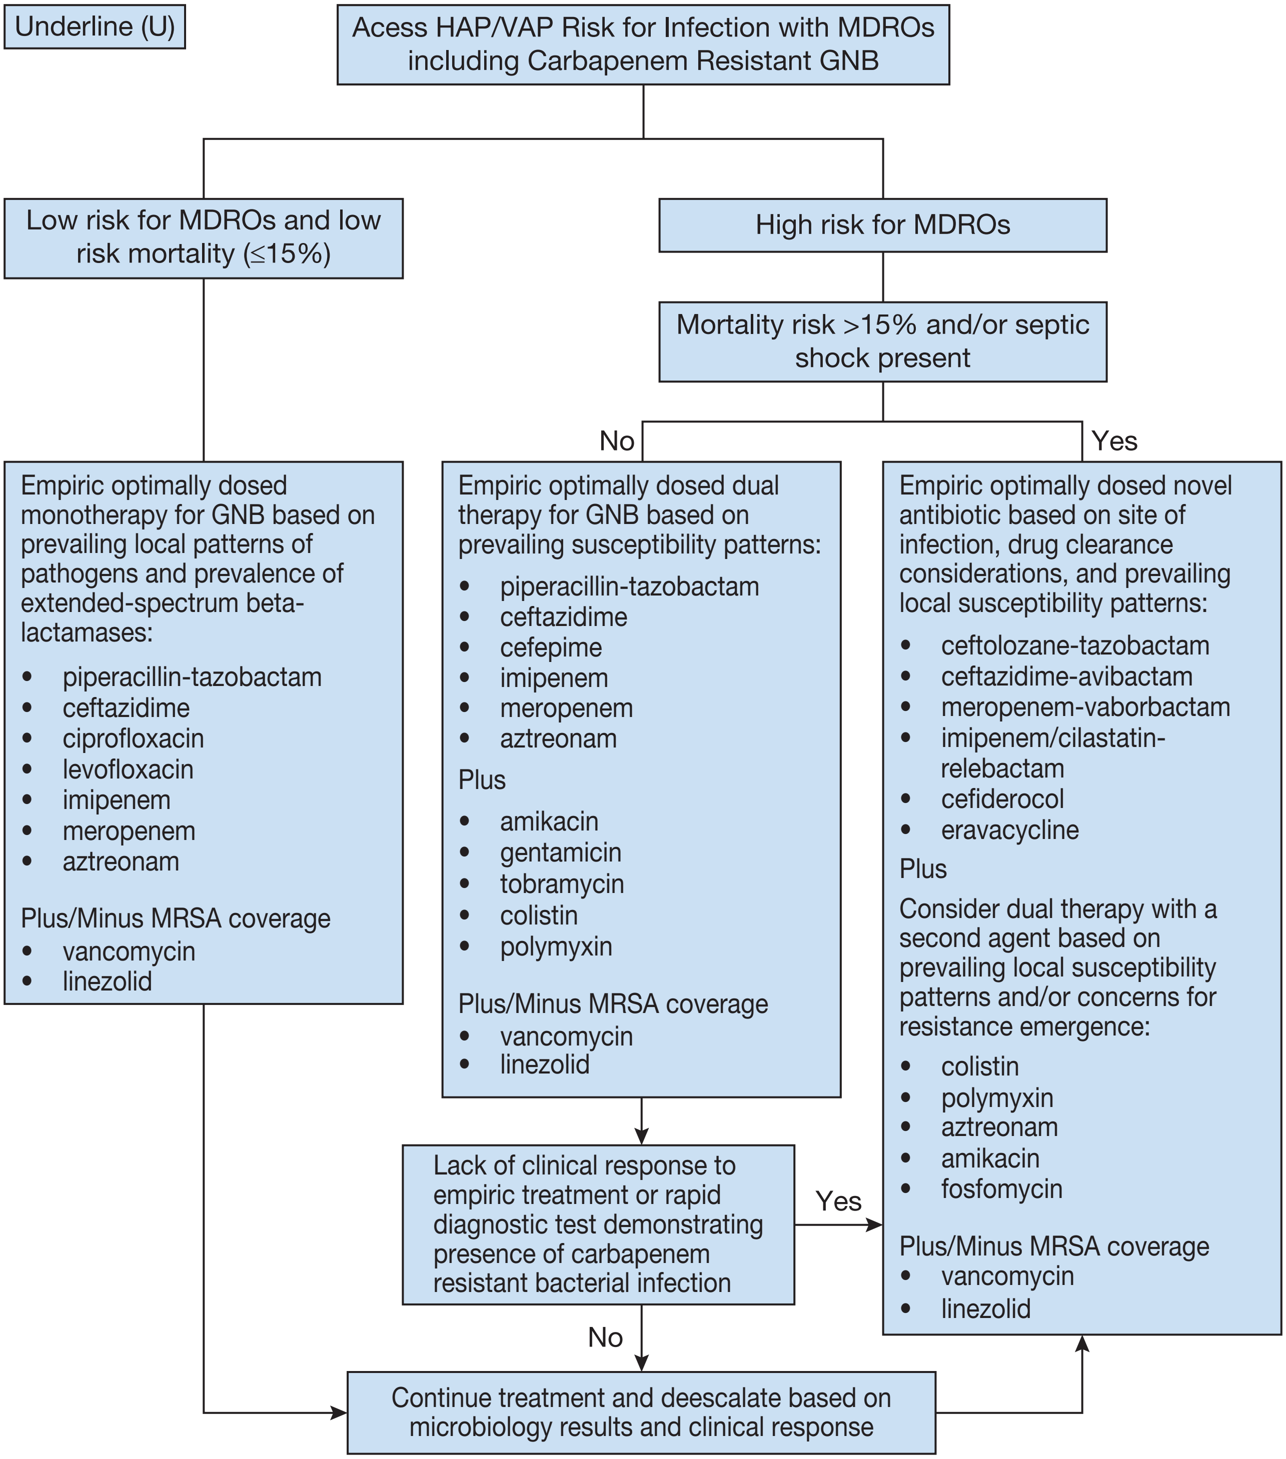
TREATMENT

When initiating empiric antibiotics for the treatment of nosocomial pneumonia, the clinician first needs to assess the patient's risk for infection with MDR microorganisms. Table 129-7 lists these risk factors.[48] Figure 129-2 lists appropriate empiric antibiotic management when HAP/VAP is suspected.

Failure to initiate the appropriate antibiotics in a timely fashion results in excess morbidity and mortality.[80–85] Inappropriate antibiotics are those that do not have in vitro activity against the offending pathogen. A large, multicenter study conducted in Spain demonstrated that in 565 cases of nosocomial pneumonia, a change in the initial empiric antibiotic regimen was required in 43.7% of cases. The most frequent reason for a change in therapy was inadequate antimicrobial coverage, which resulted in greater attributable mortality.[81] A multivariate analysis of 107 patients with VAP determined that a delay in appropriate antibiotics for ≥24 h was an independent risk factor for in-hospital mortality.[82] A separate multivariate analysis showed that prior antibiotic use was an independent risk factor for inappropriate antibiotic therapy; therefore, one should consider the possibility of drug resistance associated with previous antimicrobial agents.[62,85,116] A protocol-based approach to empiric antibiotics resulted in a greater rate of appropriate antibiotics and a reduction in antibiotic duration.[117] In addition, knowledge of each healthcare facility's antimicrobial drug resistance profile is of paramount importance.[22,23,118]

Choosing the correct dose of an antibiotic and the route of administration is essential in the treatment of nosocomial pneumonia. It is important to know the mechanism of action of each antibiotic. For example, β-lactam antimicrobial agents kill in a time-dependent fashion and require a serum concentration above the microorganism's minimal inhibitory concentration (MIC). This knowledge has led to the proposition of prolonged infusions, a practice that remains controversial.[119,120] On the other hand, aminoglycoside agents kill bacteria in a concentration-dependent manner, leading to newer extended-interval dosing parameters. Antibiotics



Underline (U)

should initially be given intravenously in all cases of nosocomial pneumonia; however, transitioning to oral therapy in certain cases has been proven to be safe and effective.[121] Finally, while traditionally thought to have a synergistic effect on the eradication of Gram-negative organisms, combination therapy rather provides a greater likelihood of appropriate empiric therapy in the case of MDR microorganisms.[122]

Aerosolized antibiotics offer an appealing treatment route as direct antibiotic delivery to the airways while avoiding systemic delivery and the associated toxicities.[123] However, the challenges accompanying aerosolizing small particles through a mechanical ventilator have limited the use of inhaled antibiotics. Two randomized controlled trials have evaluated the addition of inhaled antibiotics to standard-of-care antibiotic therapy in ventilated patients with pneumonia. One study used inhaled amikacin, while the other study used a combination of amikacin and fosfomycin, with each failing to demonstrate a difference in mortality.[124,125] While routine use of inhaled antibiotics cannot be recommended in treating HAP or VAP, their use should be considered as adjuncts in cases of pneumonia due to GNB where there is limited or no in-vitro susceptibility to available antibiotics.

When determining treatment duration for nosocomial pneumonia, the goal is to eradicate the microorganism without allowing for colonization of the host with MDR microorganisms. Clinical improvement with appropriate antibiotic therapy usually occurs in 3 to 5 days, as shown in a cohort of 63 patients with VAP in whom Clinical Pulmonary Infection Scores were obtained before and after antibiotic initiation.[126] Survivors had improving scores by day 3 compared with nonsurvivors. Currently, 7 days is a reasonable duration of treatment, but prolonged therapy should be considered in the case of *P. aeruginosa*.

A large French analysis demonstrated that patients with VAP had similar mortality and infection recurrence rates when treated with 8 days of antibiotics versus 15 days. Patients infected with nonfermenting GNB who received only 8 days of treatment had a higher infection recurrence rate compared with the prolonged therapy group, but no difference in mortality was noted.[127]

A 2013 systematic review found no mortality difference between a short course of antibiotics (7–8 days) versus a longer course (10–15 days) in the management of VAP. However, there was a strong trend toward lower relapse rates when using a longer course of antibiotics, mainly limited to VAP cases caused by nonfermenting GNB.[128] Additionally, when a 7-day course of doripenem was compared to a 10-day course imipenem–cilastatin in the management of VAP due to GNB, higher rates of clinical failure and mortality were noted, particularly in those patients infected with *P. aeruginosa*.[129] Longer durations of treatment should also be considered in patients with immunocompromise, cavitation, lung abscess, empyema, and bronchiectasis.[65] Nonresponders should be evaluated for emergence of antimicrobial resistance, extrapulmonary infection, complications of pneumonia such as empyema, and noninfectious causes of fever and pulmonary infiltrates (Table 129-8).

CONCLUSIONS

Recent epidemiologic data show that the associated morbidity, mortality, and cost of nosocomial infection, and pneumonia in particular, remain stubbornly high. This is expected to continue to be a substantial problem across the healthcare system, as the number of patients with complex chronic illnesses and the use of invasive devices increase. Diagnosis remains challenging, particularly in the nonintubated patient. Further innovations are needed in the engineering of invasive devices such as mechanical ventilators and endotracheal tubes in order to minimize nosocomial pneumonia, as are innovations in diagnostic tests that can obtain a more rapid and accurate microbiologic diagnosis. Multidrug-resistant infections are on the rise; therefore, antibiotic stewardship and development of a pipeline of new antibiotics remain high priorities. Bundled prevention strategies are an area of progress and have been successfully implemented in the ICU to reduce the rate of nosocomial pneumonia. A further understanding of the cellular and molecular interactions between host cells, pathogens, microbiota, and the environment has the potential to unlock future diagnostic and therapeutic advances.

CHAPTER 130

Tuberculosis

Akash Gupta
Karen R. Jacobson

INTRODUCTION

Tuberculosis (TB) is a severe and contagious disease caused by *Mycobacterium tuberculosis* complex (MTBC). Most often involving the lungs, TB is transmitted by cough, with an infectious dose of less than 10 bacteria.[1] Case fatality rates in untreated active pulmonary TB approach nearly 60%.[2] Starting in the 1940s, major medical advances brought effective treatment capable of curing the vast majority of clinical cases.[3,4] TB continues to cause more than a million deaths worldwide every year. The morbidity and mortality burden of TB is unevenly distributed throughout the globe, disproportionately affecting those living in poverty and those from resource-limited settings.[5]

EPIDEMIOLOGY AND MICROBIOLOGY

In this section, aspects of the epidemiology and microbiology of TB are presented.

Global Burden of TB and Recent Progress

In 1990, the World Health Organization (WHO) declared TB a global emergency. In response, the WHO endorsed the directly observed therapy strategy (DOTS), promising to "Stop TB" by finding and treating infectious cases in resource-limited settings.[6,7] Within a few years of its design, the World Bank labeled the DOTS strategy the most cost-effective health intervention ever deployed.[8,9] By 2020, an estimated 60 million lives had been saved.[10] Since 2004, TB incidence has been slowly falling every year, with an estimated reduction of 2.3% between 2018 and 2019.[10] The Joint United Nations Programme on HIV/AIDS set the 90/90 goals, aiming to reach at least 90% of people with TB and ensure that at least 90% of them have a successful treatment completion.[11] However, at the current pace, it is unlikely that these goals will be met by 2030 as originally proposed. Furthermore, these gains may be set back by disruption to TB control services during the COVID pandemic.[10]

Although global TB incidence is falling, TB remains one of the leading causes of global infectious mortality, and the 10th leading cause of death worldwide.[10,12,13] In 2019, there were an estimated 10 million new TB cases, with 1.2 million deaths among HIV-negative people, and an additional 208,000 deaths among HIV-positive people. Moreover, many TB deaths occur in young, previously healthy adults, and as such, in 2019 TB was the 9th leading cause of lost disease-adjusted life years (DALYs).[7,14]

Poverty and TB

Globally, TB disproportionately impacts those with greater poverty and lower human development indices.[15–18] Population health factors such as water sanitation, childhood immunization rates, and life expectancy also independently predict TB incidence.[19,20] The vast majority of the global burden of TB is concentrated in low- and middle-income countries (LMICs), with 28 of the 30 highest-burden countries located in Africa and Asia[10] (Fig. 130-1, Table 130-1).

Vietnam	176	170,000
Zambia	333	59,000
Zimbabwe	199	29,000

Data from Global Tuberculosis Report, World Health Organization; 2020. Available at: https://apps.who.int/iris/bitstream/handle/10665/336069/9789240013131-eng.pdf.

■ HIV and TB: Co-pandemics

HIV-induced immune suppression increases the risk of progression to active TB nearly 100-fold.[21–25] Worldwide, TB is the most common opportunistic illness and the leading cause of death in patients with AIDS.[26] HIV coinfection complicates 8.2% of all TB cases worldwide as of 2019.[10] As both a potent and common risk factor, HIV contributes substantially to TB incidence, especially in Sub-Saharan Africa.[2,27]

■ Drug-resistant TB

In 2019, there were more than 360,000 cases of multidrug-resistant (MDR) TB, defined by resistance to the two most important first-line antimicrobials, isoniazid and rifampin (rifampicin).[10] MDR-TB accounted for approximately 3.3% of newly diagnosed TB cases and 18% of relapsed cases globally. These proportions have overall remained stable. Eastern European countries have particularly high rates of MDR-TB; this is a phenomenon considered linked to the underinvestment in national TB programs and the social disruption that occurred following the collapse of the Soviet Union in the 1990s.[28] These factors are believed to have led to MDR-TB strains successfully circulating in those countries. MDR-TB is much more challenging to treat than drug-susceptible TB, with long treatment courses, higher cost, and worse treatment outcomes. However, newer regimens already have reduced, and may continue to reduce, the required treatment duration, efficacy, and total cost.[29,30] Extensively drug-resistant TB (XDR-TB) until 2021 was defined as TB resistant to rifampin, isoniazid, any fluoroquinolone, and any second-line injectable agent. There were 12,350 cases of XDR-TB reported worldwide in 2019 by this older definition, with cases in all WHO regions.[10] In 2021, the World Health Organization formally introduced the definition of pre-XDR-TB as strains that are MDR or rifampin-resistant TB and resistant to any fluoroquinolone. XDR-TB was updated as MDR or rifampin-resistant TB plus resistance to any fluoroquinolone and at least one additional group A drug, which are the most potent drugs in the ranking of second-line medicines[31]. Group A drugs may change over time as more potent options are found or resistance profiles change, so specific drugs were not named. Current group A drugs include bedaquiline and linezolid.[32]

■ Newer Threats to Global TB Control

Diabetes, smoking, alcohol, and malnutrition also can impair immunologic containment of TB infection. Their prevalence continues to increase globally, and the cumulative impact threatens global TB control in the future.[9,16,33] Among HIV-negative individuals in 2015, alcohol use accounted for 11.4% of global TB deaths, diabetes accounted for 10.6%, and smoking accounted for 7.8%.[34] These comorbidities have larger population impact on TB outcomes in many of the middle income countries including India, China, and Brazil where HIV is less prevalent.

■ TB Epidemiology in the United States: Historic Perspective

In the first half of the 20th century, TB was a leading cause of morbidity and mortality in the United States. In 1920, pulmonary TB accounted for nearly 1 in 13 deaths, outranking cancer.[6,35,36] Improvements in social conditions and population health during the early 20th century led to significant reductions in TB incidence. With the introduction of effective chemotherapy in the 1950s, incidence declined even further.[4] By the 1970s, TB incidence in the United States had reached historic lows, less than 10 cases per 100,000 people, and TB seemed on the brink of elimination. Unfortunately, public health funding for TB control was then greatly reduced, and by the mid-1980s, a nationwide resurgence ensued, particularly in the major urban centers and partially driven by HIV.[6,37,38] It is estimated that this resurgence resulted in 67,000 more cases of tuberculosis than would have occurred had the strategy designed by the CDC and its Advisory Council for the Elimination of Tuberculosis been successfully implemented.[37,39]

■ Current U.S. Trends in TB Epidemiology

With renewal of government investment in the mid-1990s, TB control was reestablished, and TB rates have since declined every consecutive year in the United States (Fig. 130-2). Since 2010, TB incidence has decreased by an average of 2% to 3% annually. In 2020, there were 7163 total reported cases of TB in the United States, or 2.2 cases per 100,000 people, which was 20% lower than 2019, although this was likely driven by multiple factors including lower detection, underreporting, and lower immigration in the setting of the COVID-19 pandemic.[40]

TB remains a concern within specific demographic groups. Non-U.S.-born individuals, especially newly arrived immigrants,

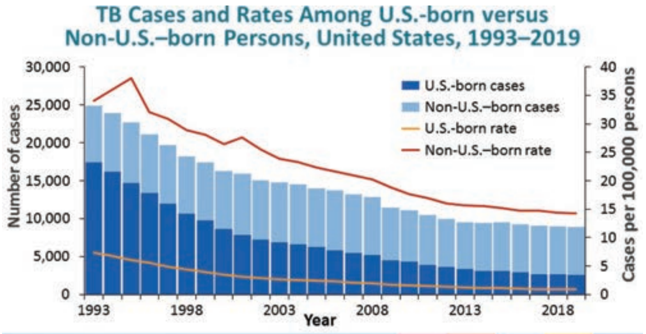

Figure 130-2 TB cases and rates among U.S.-born versus non-U.S.-born persons, United States, 1993 to 2019. *(Reproduced with permission from Tuberculosis in the United States 2019 Slide Set, Centers for Disease Control & Prevention.)*

account for the majority of TB cases in the United States, representing 71% of all U.S. cases in 2020 (Fig. 130-3). During 2019 and 2020, the most frequently reported countries of birth among non-U.S.-born persons with tuberculosis were Mexico, the Philippines, India, Vietnam, and China.[40] In non-U.S.-born residents, TB usually represents reactivation of infection acquired in TB-endemic countries prior to arrival, rather than new infection resulting from local transmission.[41] Overwhelmingly these individuals develop TB in the first years after their arrival; studies have shown that TB disease is uncommon (0.8%) more than 15 years after initial exposure.[42]

Among the U.S.-born individuals with TB disease, 36% identified as Black, 24% as Hispanic, and 4% as American Indian/Alaska Native (AI/AN).[43] Risk factors for TB in the United States include incarceration, history of alcohol or illicit drug use, and experiencing homelessness.[39,41,44–46] In these groups, "mini" outbreaks of TB resulting from recent transmission have been seen. Because TB disease in children often occurs sooner after initial infection, childhood TB incidence reflects ongoing community TB transmission and is an important indicator of TB control. In the United States, almost 80% of childhood TB occurs in U.S.-born children, although they may be in families with non-U.S.-born members.[41]

■ Microbiology of Tuberculosis

Mycobacterium tuberculosis was first conclusively demonstrated as the causal agent of TB in 1882 by Robert Koch, earning him a Nobel Prize in 1905.[47] *M. tuberculosis* is a slender, slightly curved, rod-shaped bacillus averaging 3 × 0.3 μm in size, which is visible by light microscopy. It is nonmotile, nonencapsulated, and non-spore-forming. *M. tuberculosis* is strictly aerobic.[48,49] Traditionally, mycobacteria are grown on solid, enriched media where rough, pigmented colonies generally appear 4 to 6 weeks after inoculation. MTBC can also be cultivated in specialized liquid media where characteristic "cords" visible by light microscopy are formed. Rapid liquid culture systems (e.g., BACTEC) have been adapted for use with mycobacteria and shorten time to detection of growth to as little as 9 to 16 days, depending on the initial concentration of the bacteria in the specimen tested.[50,51]

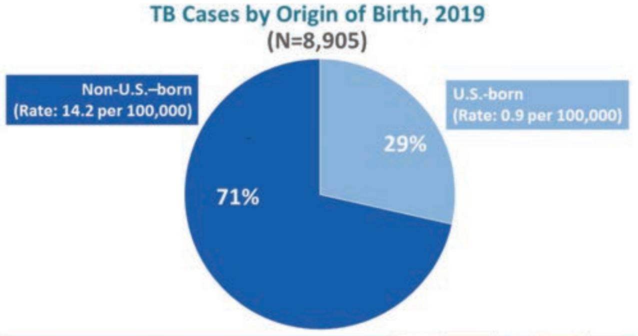

Figure 130-3 TB cases by origin of birth, 2019. *(Reproduced with permission from Tuberculosis in the United States 2019 Slide Set, Centers for Disease Control & Prevention.)*

MTBC

Eight closely related mycobacterial species capable of causing human TB have been identified and together they comprise the MTBC: *M. tuberculosis* (Koch bacillus), *M. bovis* (agent of bovine TB), *M. caprae* (bovine TB), *M. africanum* (a cause of human TB in West Africa), *M. microti* (agent of rodent TB), *M. pinnipedii* (agent of TB in seals, and a rare zoonotic disease in marine biologists attending to them), and *M. canettii* (rare cause of human TB in East Africa) (Table 130-2).[50,52,53]

Of these eight species, *M. tuberculosis* causes the vast majority of TB today. In the early 20th century, *M. bovis* accounted for up to 20% of all cases of human TB, but *M. bovis* now causes less than 2% of reported TB cases in the United States due to modern surveillance of animal herds and widespread use of milk pasteurization.[43,54,55] Sporadic outbreaks of *M. bovis* infection still occur in the United States, and ongoing surveillance is important for food-chain safety. Human-to-human transmission of *M. bovis* has been demonstrated.[56]

■ Mycolic Acid and the *Mycobacterium* Genus

The MTBC are members of the diverse *Mycobacterium* genus. The outstanding feature of the mycobacteria is their lipid-rich cell wall containing very high concentrations of mycolic acids.[48,49,51,57] This cell wall prevents reliable uptake of Gram stain. With phenol additive, mycobacteria can eventually be stained to facilitate light microscopy. Once stained, removal of dye is extremely difficult, resisting even acid alcohol wash (hence "acid-fast bacilli" [AFB]). Lipids in the mycobacterial cell wall also help resistance to drying, a property that allows MTBC to retain infectiousness even within dried droplet nuclei. The metabolic investment required to produce mycolic acids significantly slows growth rate[51] and prolongs the time to detection in incubated clinical specimens submitted to laboratory.[48] The mycolic acid–containing cell wall is also a major virulence factor, helping mycobacteria avoid innate immune defenses and intracellular killing by nonactivated host phagocytes.[58]

TABLE 130-2 Members of the Mycobacterium Tuberculosis Complex (MTBC)[a]

Species	Primary Reservoir Host	Geography
M. tuberculosis	Humans	Worldwide
M. bovis	Cattle, deer, elk, bison, badger, opossum	Worldwide
M. caprae	Goats	Worldwide
M. africanum	Human	West, Central Africa
M. microti	Vole, rodents	
M. pinnipedii	Seal, sea lion	
M. canettii	Human	East Africa

[a] *While all members of the MTBC can infect humans, some are zoonotic diseases.*

Comparison with Other Mycobacteria

The nontuberculous mycobacteria (NTM) are free-living saprophytic bacteria, commensal inhabitants of the soil and/or aquatic environments (Chapter 131). The NTM are nontransmissible from human to human under ordinary conditions, and only rarely infect humans as opportunists. In contrast, MTBC are highly transmissible, obligate primary pathogens without an environmental reservoir.[50]

Transmission

Important considerations for TB transmission are discussed below.

Droplet Nuclei

In the late 1930s, William Wells, a sanitation engineer at Harvard University, first conceived of “droplet nuclei” for airborne transmission of infectious diseases.[59] He found that forceful expiratory efforts, such as coughing and sneezing, discharge minute respiratory droplets of sputum containing viable bacilli that, when increasingly reduced in size by evaporation, become infectious droplet nuclei, each measuring less than 5 µm.[60] Certain healthcare procedures, for example, bronchoscopy, sputum induction, autopsy, and even irrigation of abscesses, also produce infectious droplet nuclei.[61]

Due to small size, droplet nuclei have an extremely slow settling rate in air (0.5 mm/s or less), permitting their transport over significant distances by air currents. Larger respiratory droplets, on the other hand, settle out of the air quickly, and travel only a few feet from the source case. The microbes suspended within droplet nuclei are highly susceptible to germicidal levels of ultraviolet light.[2,62] The small size of droplet nuclei also facilitates penetration of the bronchial defenses, allowing access to terminal alveolar macrophages. The fairly tortuous and branched path of the pharynx and bronchial tree ensures that larger respiratory droplets are instead deposited on the mucosal lining of the airway or trapped in the mucociliary elevator and expelled[60] (Table 130-3).

Airborne Transmission of TB

In the 1950s, Richard Riley, a medical student working with Wells, elegantly demonstrated that TB is near exclusively transmitted by droplet nuclei. Riley commandeered a TB ward of six rooms for his study. The air from each individual room was ventilated to an upper chamber, where caged guinea pigs were kept, sometimes passing through an adjustable UV light source.[63] Guinea pigs are considered uniquely susceptible to infection with *M. tuberculosis*, even by dilute aerosols, and their use allowed quantification of degree of patient infectiousness.

Relatively few respiratory diseases are preferentially transmitted via the airborne route; these include TB, measles, varicella, and smallpox. Most infectious respiratory diseases (including, e.g., pertussis, influenza, the common cold, and pneumococcal pneumonia) are instead transmitted by direct contact with larger respiratory droplets leading to colonization of the host nasopharynx before subsequent lung invasion. There is evidence that SARS-CoV-2, the virus that caused the COVID-19 pandemic, can be transmitted by both larger respiratory droplets and by airborne droplet nuclei.[64]

TABLE 130-4 Factors Associated with TB Transmission and Number of Infectious Droplet Nuclei per Volume of Air

Characteristics of Source Case	Environmental Factors
Sputum-smear positivity for AFB	Air circulation, ventilation
Cough strength and frequency	Room volume
Presence of lung cavitation	Humidity
Effective treatment	UV light
Delayed diagnosis	Proximity to the source case
Laryngeal tuberculosis	Duration of contact with infected air

Data from Sepkowitz KA. How contagious is tuberculosis? Clin infect Dis. 1996;23(5):954–962.

Risk Factors for TB Transmission

The risk of TB infection is a function of exposure to the tubercle bacilli. In turn, this depends on the interaction of three factors: infectiousness of the source case, a conducive environment to airborne transmission, and host susceptibility (Table 130-4).

Source Case Infectiousness

An important finding from Riley’s studies was the extreme variability in infectiousness of TB patients.[65,66] The dominant predictors of infectiousness in source cases are the presence of cough, lung cavitation on chest radiograph, and acid-fast bacilli visible in sputum by smear microscopy. Sputum-smear microscopy positive cases excrete about 108 bacilli per mL of sputum compared with less than 103 bacilli per mL of sputum in smear-negative cases.[61] About 35% of close contacts of sputum smear–positive patients will become infected, compared to less than 10% from sputum smear–negative cases[61,67–69] (Fig. 130-4).

Riley also demonstrated that effective anti-TB treatment could rapidly render patients noninfectious, usually within a few days of initiation.[70] These findings guide the discontinuation of hospital

TABLE 130-3 Key Distinguishing Features of Transmission from Droplet Nuclei and Respiratory Droplets

	Droplet Nuclei Transmission	Respiratory Droplet Transmission
Particle size	1- to 5-µm-diameter particles (dried residua of larger particles)	>100 µM-diameter particles
Time for article to settle out of air	Suspended indefinitely	Settle within seconds, 1 m from source
Number of microbes per particle	Contain few microbes	Contain many microbes
Site reached by particle in recipient airway	Alveolar deposition	Upper airway deposition
UV-light susceptibility	Susceptible	Resistant
Example pathogens	Measles, TB, varicella, SARS-CoV-2	RSV, SARS-CoV-2, influenza, *Staphylococcus*

Modified with permission from Garay S, Rom W. Tuberculosis, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.

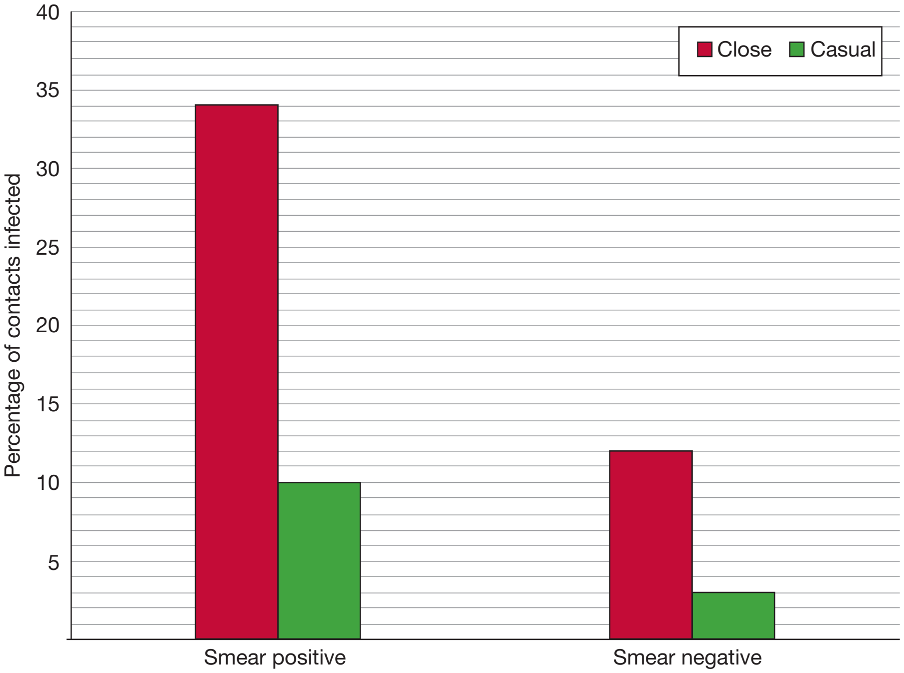

Figure 130-4 Infectiousness of tuberculosis by bacteriologic status of and proximity to source case. *(Reproduced with permission from Grzybowski S, Barnett GD, Styblo K. Contacts of cases of active pulmonary tuberculosis. Bull Int Union Tuberc. 1975;50(1):90–106.)*

isolation.[71] As a matter of convention, pulmonary TB patients are usually considered noninfectious after 2 weeks of effective chemotherapy, provided drug resistance and nonadherence are excluded.[72]

Conducive Environment

Important environmental factors influencing TB transmission include ventilation (or room air changes per hour) and ultraviolet light.[61,73,74] Proximity and duration of contact with source case are also determinants of TB transmission. Household contacts are several times more likely to be infected than are casual contacts from the community.[61,68] Thus crowded housing with poor ventilation and inadequate natural lighting—such as occurs in prisons, homeless shelters, and the large urban slums of the developing world—are particularly conducive for TB spread.[15,75] Recent data has shown that in high-burden settings, molecular epidemiology studies among household clusters show mismatch.[76] Newer models from molecular epidemiology suggest that only 8% to 19% of transmission to adults occurs within the household, or between known social contacts. The rest are thought to be from community contacts in high-burden settings.[77]

Host Susceptibility

Genetic determinants of innate immunity are likely important to host susceptibility, but they are poorly understood.[58,78] Vaccination with attenuated *M. bovis* Bacille Calmette-Guérin (BCG) strain probably does not reduce the risk of infection with MTBC, even if it does reduce the subsequent chance of developing disseminated active disease once infected.[61,78,79] Some studies suggest that previous TB infection (as manifested by tuberculin skin test positivity) may partially protect against reinfection, although the degree of protection has not been quantified.[80–82] Other studies have shown in high-TB-burden settings that having had TB previously increases individual risk of recurrent disease; it is unclear if this is still modified by some level of protection.[83]

NATURAL HISTORY AND PATHOPHYSIOLOGY OF TB INFECTION

It is estimated that about 25% of the world's population is infected with latent TB.[84] However, only a small fraction of these individuals will develop active TB; most infections remain latent without apparent ill effect on the host. Risk factors associated with progression to active disease once infected are shown in Table 130-5.

From Exposure to Infection and the Innate Immune Response

The natural history of TB infection is outlined in Fig. 130-5. Following exposure to an infectious source case, many contacts do

TABLE 130-5 Common Risk Factors for Increased Likelihood of Progression from Latent Tuberculosis Infection to Active Tuberculosis Disease

Exposure to pTB (close contact)
Cavitation, sputum smear status of source
Ventilation, UV-light in environment
Duration and intimacy of contact
Previous infection
Unable to reach terminal alveolar macrophages No TST conversion
Macrophage infection with immediate clearance No TST conversion
Infection established (~30% of exposed) TST conversion
Not infected (~70% of exposed)
Innate immune factors
Containment (90–95%) "Latent TB Infection"
Early progression to active TB within 2 Years (5–10%) "Primary TB"
Adaptive immune dysfunction
Nutritional condition
Substance use
Vitamin D status
Age at infection
Continued containment (85–90%) "Latent TB Infection"
Late progression-reactivation TB after 2 years (5%) – "Post Primary"
Acquired adaptive immune dysfunction
Nutritional condition
Comorbid disease
Substance use
Vitamin D status
Age-related immune senescence

Figure 130-5 Natural history of TB infection. pTB, pulmonary tuberculosis; TST, tuberculin skin test. *(Data from Comstock GW. Epidemiology of tuberculosis. Am Rev Respir Dis. 1982;125(3 Pt 2):8–15.)*

not become infected, and will not convert their TST—either because infectious droplet nuclei did not reach their terminal alveoli or because any successful invaders were immediately cleared by intrinsic microbicidal activity of macrophages.[3]

However, in those who become infected, invading mycobacteria engulfed by alveolar macrophages manage to evade intracellular killing. Mycobacteria bypass innate immune mechanisms and replicate without limitation, spreading to regional lymph nodes, and silently disseminate hematogenously.[1,52,78] After a few weeks, dendritic cells are activated and produce cytokines, such as tumor necrosis factor α (TNF-α), which recruit blood-borne monocytes and lymphocytes to sites of infection, setting the stage for the adaptive cellular immune response.[78]

The Adaptive Immune Response and Containment of Mycobacterial Infection

The main effectors of the adaptive, cell-mediated immune (CMI) response to mycobacteria are the CD4-positive subset of T lymphocytes. Once stimulated, T lymphocytes release their own battery of cytokines (including interferon γ [IFN-γ]) that serve to reciprocally activate infected macrophages and trigger enhanced intracellular mycobacteria killing. This is the basis for both the tuberculin skin test and IFN-γ release assays, which become positive with the development of a host CMI response. Over the next few weeks, the CMI directs necrotizing granuloma formation, which usually contains bacillary replication.[78]

Primary Disease

About 5% of immune competent individuals do not control initial mycobacterial replication and instead progress to primary TB disease, usually within 18 months. The risk of progression to primary disease is even higher in those with compromised CMI or other risk factors. Primary disease may occur at the initial site of lung entry (typically the mid and lower lung zones where greater airflow directs droplet nuclei deposition), regional lymph nodes, or rarely at metastatic sites initially seeded during early occult hematogenous dissemination.[78]

Reactivation Disease from Latent Infection

For the individuals who successfully contain the initial infection and avoid primary disease, mycobacteria lie latent within healed, fibrotic, and/or calcific granulomata. At this stage, mycobacteria cannot be cultured from host sputum or tissue specimens and symptoms are not present.

Historically, TB has been perceived to exist in one of these two states: latent or active. However, recent research has demonstrated that TB infection often exists along a continuum between these two states, based on the degree of mycobacterial activity and immune response at a given moment. Some have suggested adding "incipient TB," or TB that is likely to progress to active disease but is not yet detectable by symptoms or conventional diagnostics, and "subclinical" TB, or TB that produces abnormalities detectable by diagnostics but has not yet produced symptoms.[85,86]

Caseation and Cavitation

Differences in quality of host adaptive immune response determine clinical presentation.[52,78] Some individuals develop a particularly robust, caseating granulomatous inflammatory response with resultant tissue destruction and lung cavitation—they discharge large amounts of bacilli into airways and are highly contagious. At the other end of the spectrum, a severely weak or immature granulomatous response allows hematogenous dissemination of bacilli, accompanied by widespread inflammatory foci of poorly formed granulomas. Each focus typically enlarges to about 3 mm in size, or about the size of millet seed. This severe form of TB (miliary TB) has a high case-fatality rate.

CLINICAL MANIFESTATIONS

TB has had a number of illuminating vernacular names through history. In ancient Greece, TB was called "phthisis" meaning to waste away. In Rome, "tabes" was used, indicating wasting and overall decay. "Consumption," a term applied to TB in 19th century England is particularly evocative, referring to the observation that TB sufferers appear to be gradually "consumed" by the disease, becoming lighter and less robust over months.[87]

TABLE 130-6 Proportion of Reported TB Cases in the United States, by Predominant Site of Disease, 2019

	Site or Type of Disease	Percentage (%)
Pulmonary		79.4
Extrapulmonary	Total	20.6
	Pleural	4.0
	Lymphatic	7.6
	Meningeal	0.9
	Peritoneal	1.3
	Bone and joint	1.8
	Genitourinary	0.9
	Other	5.3

■ Site of Disease and Clinical Presentation

TB is predominantly a respiratory disease, affecting the lungs in about 80% of cases[43,88] (Table 130-6). About 30% of TB cases involve an extrapulmonary site, occurring either with or without concomitant lung involvement; this percentage is higher (generally closer to 50%) in immunocompromised patients. TB can affect virtually any organ, although peripheral lymph nodes and pleural space are the most common extrapulmonary sites.[89]

Classically TB presents insidiously over weeks, with persistent local symptoms correlating to granulomatous inflammation (e.g., cough in the case of pulmonary TB, neck mass for cervical lymph node TB), as well as constitutional symptoms that correlate to the production of pyrogenic cytokines such as TNF-α (e.g., fevers, night sweats, anorexia, weight loss). Initially the cough may be dry, but after several months it becomes productive. Fever may be absent, especially in the elderly.[90] With advancing disease, hemoptysis, anorexia, and weight loss can occur.[91–93] As discussed above, some patients are asymptomatic even with clear TB disease activity demonstrable on culture or radiography—a prospect that frustrates active case finding efforts by TB control programs.[3,94] Recent work has focused on this "subclinical" phase when an individual may become infectious but remain without symptoms or symptom unaware.

■ Physical Examination

Even when relatively extensive disease is present, pulmonary TB most often produces no detectable abnormality on physical examination.[91,94] However, it is important to examine for signs of extrapulmonary disease such as lymphadenopathy, abdominal, or bone and joint involvement, particularly in HIV-infected individuals. Tachypnea and hypoxia are relatively rare, unless there is extensive lung destruction or miliary disease.

■ Chest Radiography in Pulmonary TB

Radiographic findings of TB are well described.[94–96] Sensitivity of chest x-ray for active pulmonary TB is 70% to 80%, although it is less in patients with HIV or other severe immune compromise. Chest radiography is only moderately specific and there is generally poor agreement between chest film readers.[97–99] Chest radiography alone cannot reliably distinguish between active and healed, latent TB.[97,98,100]

Typical Chest Radiograph Patterns

Four radiographic features suggest active TB: (1) nodular opacities located in the apical–posterior segments of the upper lobes or superior segment of the lower lobes, (2) associated volume loss and fibrosis, (3) lung cavitation, and (4) endobronchial spread. Endobronchial spread to dependent lung segments fills lung acinar units, resulting in 4- to 5-mm nodular opacities on plain film (acinar shadows) and a "tree-and-bud" pattern on computed tomography (CT)[95,98,101] (Figs. 130-6 and 130-7).

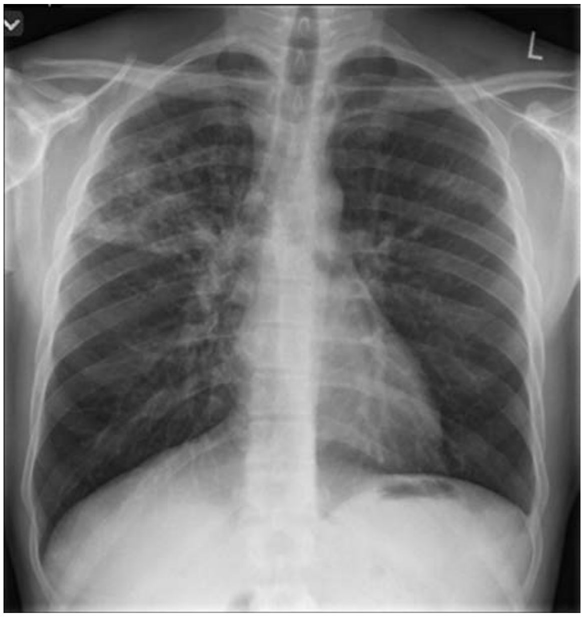

Figure 130-6 This 32-year-old male refugee recently arrived from Eritrea. He presented with persistent cough and fevers despite completing two courses of antimicrobial therapy directed against bacterial community-acquired pneumonia. Sputum sample was both smear positive and culture positive for MTBC.

Atypical Chest Radiograph Patterns

Atypical radiographic patterns are seen in children, the elderly, the immunocompromised, and those with primary disease.[96,100,102] Atypical features include lower lung zone infiltrates without cavitation, unilateral pleural effusion (Fig. 130-8), and ipsilateral hilar or

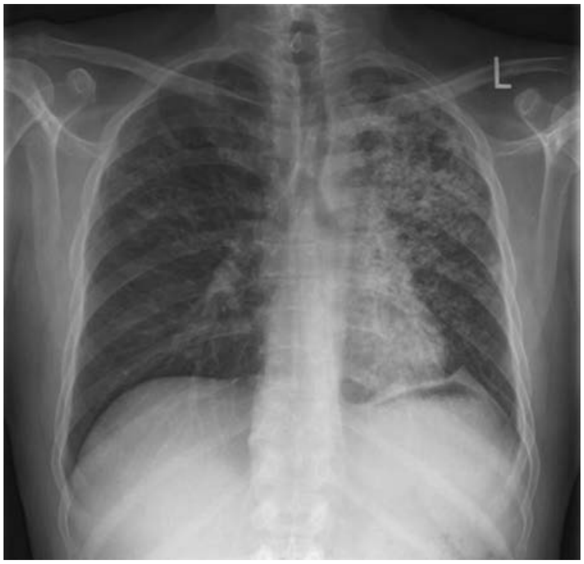

Figure 130-7 A 36-year-old man with history of homelessness. This radiograph demonstrates typical manifestations of reactivation TB: upper lobe nodular opacities, cavitation, acinar shadowing from endobronchial spread, and fibrosis.

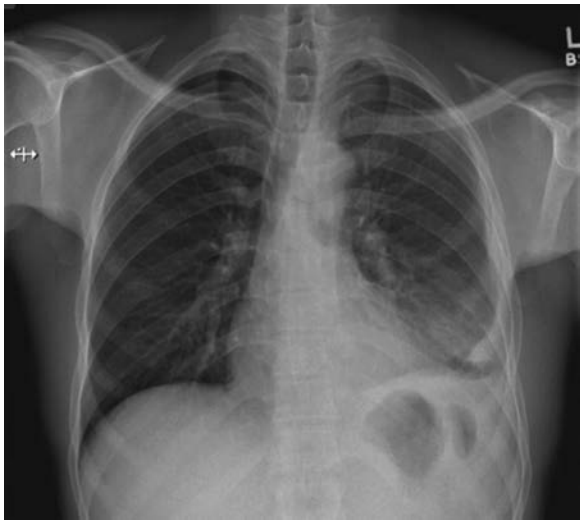

Figure 130-8 This 22-year-old man identified as a close household contact of a smear-positive case of pulmonary tuberculosis. Seven weeks later he developed fevers and cough. This radiograph demonstrates unilateral pleural effusion with compressive atelectasis. Diagnostic thoracocentesis revealed a transudate with cellular infiltrate, predominantly lymphocytic. Sputum was culture negative for mycobacteria, but pleural specimen eventually grew MTBC.

mediastinal adenopathy (Fig. 130-9). Intrathoracic TB lymphadenitis is often better appreciated on CT, with characteristic features including lymph node enlargement, rim enhancement, and low central attenuation.[95]

Miliary TB is rare; when present, it produces a distinctive, readily recognizable radiographic pattern: innumerable, interstitial nodules uniformly distributed throughout all lung fields, without reduction in lung volumes (Fig. 130-10).

DIAGNOSIS OF TB

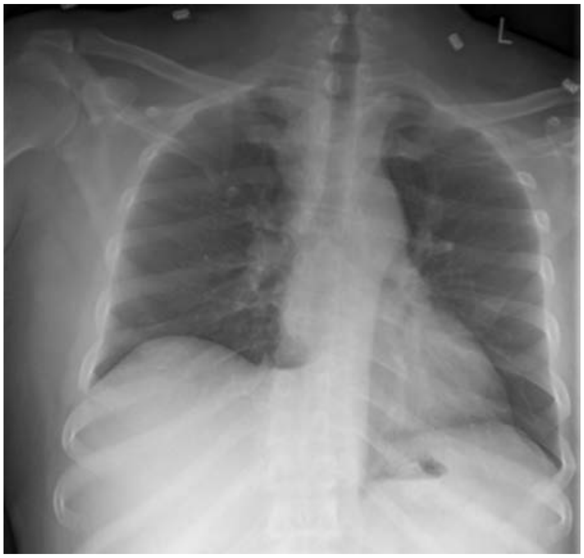

Figure 130-9 This 42-year-old HIV+ man with a CD4 count of 150 cells/mm^3 presented with cough. Significant mediastinal and right hilar adenopathy are present without apparent lung parenchymal disease. Sputum cultures were smear negative but culture positive for MTBC.

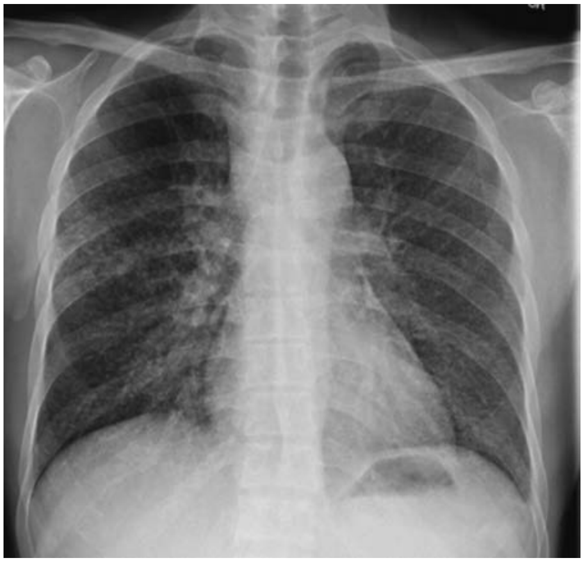

Figure 130-10 This 36-year-old HIV+ man presented with fevers. Chest radiograph identified right upper lobe infiltrate and a background miliary pattern consisting of innumerable noncalcified nodules measuring 2 to 3 mm, randomly distributed.

Most U.S. clinicians will practice for years without ever encountering a case of TB. For every 450 ambulatory visits for community-acquired pneumonia (CAP), and for every few dozen cases of lung cancer, there is on average one case of TB in the United States.[103,104] In low-incidence settings, many patients diagnosed with TB will have experienced multiple contacts with the healthcare system before the diagnosis of TB is considered.[105–107]

Thus, the diagnosis of TB requires a very high index of suspicion, considering epidemiologic risk factors and suggestive clinical–radiographic features (Fig. 130-11). Ultimately, the definitive diagnosis requires culture confirmation, although many (usually in the setting of significant risk factors) will be treated as presumed TB. In cases of high clinical suspicion due to radiologic findings, culture negative disease is the diagnosis if radiologic findings improve after treatment with tuberculosis medications.

■ Laboratory Investigations

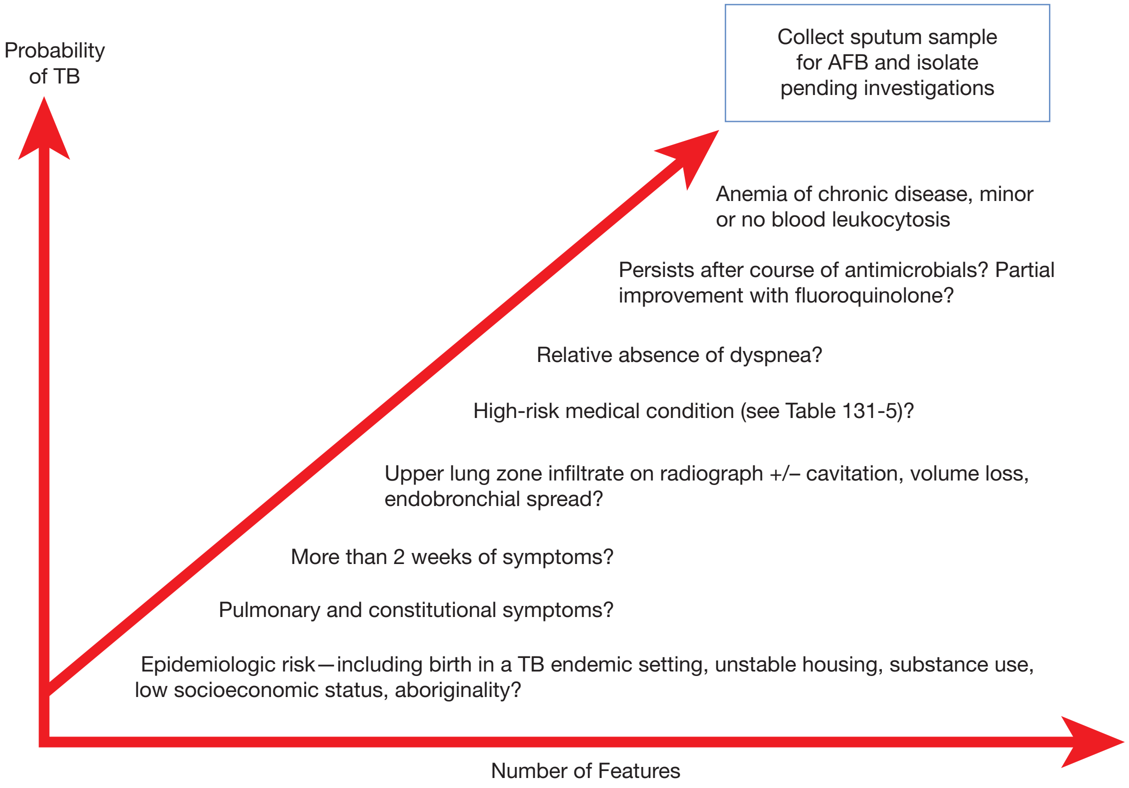
A number of laboratory studies that constitute important elements in the diagnostic armamentarium for tuberculosis are discussed below.

Specimen Collection

Protocols to ensure proper specimen handling, storage, transport, and labeling are available.[94] Ideally, specimen collection should occur before initiation of therapy to increase yield.

For the diagnosis of pulmonary TB at least three sputum samples, each 5 to 10 mL, should be collected at least 1 hour apart. For those patients unable to expectorate spontaneously, sputum induction (with nebulized hypertonic saline) or bronchoalveolar lavage (BAL) is an alternate established method.[108] Induced sputum samples produce slightly higher yield than do BAL samples (87% vs. 73%), and sputum induction is much better tolerated, less invasive, and lower cost.[109,110] If bronchoscopy is performed to evaluate other diagnostic considerations, then an additional sputum sample collected immediately after bronchoscopy may have particularly high yield for mycobacterial identification.[108] Interestingly, recent work has suggested face-mask sampling as an additional noninvasive method for detecting exhaled *M. tuberculosis*.[111]

For diagnostic confirmation of extrapulmonary TB, tissue or fluid samples should be submitted for TB smear and cultures. Gastric aspirates performed upon awakening can be helpful for the diagnosis of pulmonary TB in certain situations.[110] Specimens should be



Probability of TB
Collect sputum sample for AFB and isolate pending investigations
Anemia of chronic disease, minor or no blood leukocytosis
Persists after course of antimicrobials? Partial improvement with fluoroquinolone?
Relative absence of dyspnea?
High-risk medical condition (see Table 131-5)?
Upper lung zone infiltrate on radiograph +/– cavitation, volume loss, endobronchial spread?
More than 2 weeks of symptoms?
Pulmonary and constitutional symptoms?
Epidemiologic risk—including birth in a TB endemic setting, unstable housing, substance use, low socioeconomic status, aboriginality?
Number of Features

Figure 130-11 Clinical factors increasing index of suspicion for tuberculosis. Increasing probability of TB warrants further investigation, especially collection of respiratory samples for mycobacterial stain and culture. For hospitalized patients, or those in congregate living settings, increasing suspicion warrants prompt isolation pending results of investigations. *(Reproduced with permission of Richard Long, unpublished observations.)*

submitted as fresh (or in sterile normal saline) without addition of preservative (e.g., formalin), because this will prevent subsequent identification, culture, and drug susceptibility testing in the microbiology laboratory. It is important to notify both the laboratory and clinician before collecting a specimen if extrapulmonary TB is suspected, as the laboratory must take appropriate biosafety precautions during specimen handling to prevent laboratory transmission of TB.

Direct Microscopy for AFB

Sputum-smear microscopy is more than 100 years old but remains the most widely used investigation for active TB in many high-burden countries today.[47,112] Two methods are commonly used for acid-fast staining of mycobacteria: carbolfuchsin (e.g., Ziehl–Neelsen [ZN]) and fluorochrome-based procedures (e.g., auramine–rhodamine dye). Fluorescent methods slightly improve sensitivity over ZN and allow the use of lower microscopic magnification during inspection of the slide, significantly shortening the time required to examine an entire specimen.[113]

Sputum microscopy is widely available and low cost. It is performed directly on clinical specimens with rapid turnaround time, which facilitates prompt recognition, isolation, and treatment of infectious TB cases. Microscopy also provides prognostic information: smear-positive TB cases are more infectious and have much higher case-fatality rates if untreated than do sputum smear–negative cases, reflecting high bacterial burden and more advanced disease.[68,114,115]

However, sputum-smear microscopy has limitations. Sensitivity for pulmonary TB is only about 60% to 70%, and even lower in extrapulmonary specimens and in those with HIV coinfection. NTM also stain acid-fast, which lowers the specificity of smear microscopy.[116–118] In low TB prevalence settings, NTM are recovered from up to 9.1% of AFB smear-positive sputum samples.[119]

Mycobacterial Culture

Mycobacterial culture remains the gold standard for the diagnosis of active TB. Culture methods can detect as few as 10 viable bacilli per millimeter of sample, compared with about 100 bacilli per millimeter for nucleic acid amplification (NAAT) and 5000 to 10,000 bacilli per millimeter with smear microscopy.[94] In addition, biochemical and phenotypic testing of isolated organisms provides nearly perfect specificity, distinguishing even between individual members of the MTBC. Of particular importance, isolation of the infecting organism permits drug susceptibility testing, which can be used to guide targeted therapy. Species identification can be performed using molecular subtyping (i.e., DNA/RNA fingerprinting), high-pressure liquid chromatography, biochemical testing, or mass spectrophotometry (i.e. MALDI-TOF systems).[120–122]

Culture of MTBC from clinical specimens takes, on average, between 2 to 4 weeks, but as long as 8 weeks in some specimens with low initial concentration of organism.[123] Culture requires a level III biosafety laboratory to prevent transmission to laboratory technicians, and availability of such facilities is poor in most high-burden, resource-limited settings.

Nucleic Acid Amplification

NAAT is a useful tool in the diagnosis of TB, offering higher sensitivity than microscopy and shorter turnaround times than culture.[100,124,125] Sensitivity of NAAT in AFB smear-positive respiratory samples is excellent, usually greater than 95%.[124] However, in paucibacillary specimen types, such as AFB smear-negative sputum and extrapulmonary samples, the sensitivity is reduced to 40% to 60%, with a negative predictive value inadequate to exclude a diagnosis of TB.[126–130] Specificity of NAAT methods is very high, ranging between 90% and 100% for all specimen types.

Performance of traditional NAAT requires sophisticated laboratory facilities. However, in the last decade, several automated in-cartridge assays have become available to facilitate wider use in settings without intensive laboratory facilities. The most widely adopted have been the Xpert assays by Cepheid, including initially Xpert/MTB RIF and more recently Xpert Ultra. These were developed to allow NAAT directly from unprocessed clinical specimens, without the need for a centralized reference laboratory, even in resource-limited settings.[131–133] The Xpert/MTB-RIF simultaneously detects mutations within the mycobacterial RNA-polymerase gene that correlate with rifampin resistance, thus identifying MDR cases several weeks before culture-based testing. The WHO endorsed the Xpert/MTB-RIF assay in 2011,[134] and it was approved by the FDA in 2013.[135] The Xpert MTB-RIF *Ultra* assay was then developed to improve the sensitivity of the standard Xpert/MTB-RIF assay, and it was endorsed by the WHO in 2017 to replace the standard Xpert/MTB-RIF assay.[55,136] There are some trade-offs, however, as the Xpert Ultra assay has lower specificity, given that trace MTB DNA could be residual from prior infection that is now inactive.[133]

In addition, the MTBDR*plus* by Hain Lifescience is a molecular line-probe assay designed to detect resistance to rifampin and isoniazid,[137,138] and the MTBDRs/assay can detect resistance to fluoroquinolones and injectable agents. Neither of these assays are approved by the FDA, but the WHO does recommend their use in certain situations and they have been deployed for clinical use in certain countries, such as South Africa.[139]

Urine Antigen Detection in HIV Patients

A point-of-care assay has been developed for urine detection of a mycobacterial cell wall antigen (glycolipid lipoarabinomannan, or urine LAM). This test has been validated specifically in patients with HIV.[140,141] The WHO recommends its use for HIV-infected individuals with concern for TB and CD4 <100, or for HIV-infected patients of any CD4 count if they are seriously ill.[142] The assay has not been FDA-approved for use in the United States.

Testing for Latent TB infection

There are two main tests for the identification of LTBI: (1) tuberculin skin test (TST) and (2) IFN-γ release assays (IGRAs). Both are indirect, in that they evaluate the presence of host cell–mediated immunity rather than detect actual mycobacterial organisms or antigens.[143] As such, neither can distinguish active disease from latent infection, and neither is predictive of future risk of active TB. Both tests have very poor sensitivity and predictive value for active TB, and neither can be used to exclude a diagnosis of active TB.[144,145] These tests are better used to assess candidates for LTBI treatment (discussed below). The choice of whether to use TST, IGRA, or both is dependent on the pretest probability of infection (based on risk factors), and the risk of progression to active TB (based on immune suppression and comorbidities). Other considerations include prior BCG vaccination (favors IGRA, which are not positive from BCG exposure), likelihood of patient returning to have the test read (favors IGRA over TST), and local test and laboratory capabilities (may favor TST).[146]

Other Laboratory Findings

Anemia is commonly observed in TB, usually due to chronic inflammation or malnutrition.[94] Syndrome of inappropriate ADH can complicate pulmonary or central nervous system TB.[147] Historically, disseminated TB was an important cause of adrenal insufficiency. Hypercalcemia is a relatively frequent complication of TB.[148] Activated macrophages within granulomas upregulate 1-α-hydroxylase, which can in turn activate vitamin D and lead to an increase in calcium absorption.[149–151] Hypercalcemia of TB can be symptomatic and occasionally leads to nephrocalcinosis, nephrolithiasis, or acute volume depletion. Vitamin D supplementation during TB therapy may increase the risk of hypercalcemia.[152]

MANAGEMENT OF ACTIVE TB

Prior to the availability of chemotherapy, prevailing wisdom prescribed fresh air, nutrition, sunlight, and rest for treatment of TB. In 1947, clinical outcomes of smear-positive pulmonary TB patients treated at a sanatorium in the United Kingdom were recorded: within 4 years of entry, 55% died, 20% remained chronically affected, and 25% experienced remission.[153] With the discovery of medications for treatment of TB, mortality dropped by orders of magnitude, and within a decade TB sanatoria were shuttered.[6,154]

■ Principles of TB Therapy

The aims of TB therapy are to (1) interrupt transmission by rapidly rendering patients noninfectious, (2) relieve symptoms and prevent mortality, (3) prevent the emergence of drug resistance, and (4) prevent future relapse by providing a definitive cure.

To achieve these aims, treatment regimens must include combination of potent bactericidal drugs that are provided for a minimum of 6 months based on current guidelines, although recent research suggests a possible 4-month regimen may be equally effective.[155] The choice of regimen should be guided by the results of drug susceptibility testing after they become available. TB regimens are divided into an initial intensive phase, designed to quickly reduce large bacillary burden, followed by a prolonged continuation phase that consolidates antimycobacterial killing while allowing intermittent dosing and lower pill burden. A high level of adherence is required to prevent relapse and emergence of resistance. Rifamycins (rifampin, rifampicin, rifabutin) have a critical role in preventing relapse and whenever possible should be provided throughout the treatment. Several randomized clinical trials have established standardized treatment regimens as outlined in Table 130-7. Reported success rates with these regimens approach 95% in the United States.[156]

■ First-line TB Drugs

Current first-line TB drugs include isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) (Table 130-8).

INH, first introduced in 1952, remains a cornerstone of TB treatment. It has potent bactericidal activity and causes rapid decline of sputum bacillary load within days of administration, rapidly reducing infectiousness.[157] INH is generally well tolerated but can cause hepatotoxicity, requiring cessation of therapy in a small subset of patients. Risk factors for severe INH-related hepatotoxicity include older age and pre-existing liver diseases.[158] Peripheral neuropathy can develop in elderly, malnourished, or diabetic patients taking INH, but this risk is lowered with concomitant administration of pyridoxine (vitamin B6).

RIF revolutionized TB therapy following its introduction in 1968 and has since become a critical component of modern, short-course TB regimens.[157,159,160] RIF and other rifamycins appear to have unique relapse-preventing properties that allow the duration of chemotherapy to be shortened to 9 months or less. Until recently, without RIF, relapse rates are unacceptably high, and treatment duration must be significantly extended. New regimens do hold promise for a 6-month course with three novel agents, but those are still in trials and not yet widely available.[161]

RIF is very well tolerated in the vast majority of patients. Rarely, hypersensitivity reactions occur, including thrombocytopenia, flu-like syndrome, and neutropenia. RIF is a strong inducer of the cytochrome p450 oxidation system (CYP450) and interacts with a multitude of other medications.[162] RIF produces a benign orange-red discoloration of body fluids (urine, tears, sputum, feces, sweat) and can permanently stain contact lenses and dentures.

TABLE 130-7 Drug Regimens for Treatment of Active Tuberculosis in Adults, Caused by Susceptible Organism

	Intensive Phase (8 Weeks)	Continuation Phase	Comments
Regimen 1	INH + RIF + PZA + EMB[a] Given daily or 5×/week	18 weeks INH + RIF Given daily or 5×/week[b]	Preferred regimen for patients with newly diagnosed tuberculosis. Extend continuation phase to 7 months if risk of relapse present.[b]
Regimen 2	INH + RIF + PZA + EMB[a] Given daily or 5×/week	18 weeks INH + RIF 3×/week	Preferred alternative in situations in which more frequent DOT during continuation phase is difficult.
Regimen 3	INH + RIF + PZA + EMB[a] Given 3×/week	18 weeks INH + RIF Given 3×/week	Caution in patients with HIV and/or cavitary disease. Missed doses increase risk of treatment failure, relapse, drug resistance.[e]
Regimen 4	INH + RIF + PZA + EMB[a] Given daily × 2 weeks, followed by 2×/week for 6 weeks	18 weeks INH + RIF Given 2×/week	Not eligible for this regimen if HIV-infected, or if smear-positive and/or cavitary disease. If missed doses, equivalent of weekly therapy, which is inferior.

INH, isoniazid; RIF, rifampin; PZA, pyrazinamide; EMB, ethambutol; DOT, directly observed therapy.

[a] *EMB is given pending results of INH susceptibility testing—if isolate confirmed fully susceptible then EMB is discontinued.*

[b] *Risk factors for relapse include cavitation on chest radiograph, extensive pulmonary disease, culture positive after 2 months of therapy, poorly controlled HIV infection, diabetes, or other immunosuppressing condition.*

Note: Pyridoxine (vitamin B6), 25–50 mg/day, is given with INH to all patients at risk of neuropathy. For patients with peripheral neuropathy, experts recommend increasing pyridoxine dose to 100 mg/day.

Data from Nahid P, Dorman SE, Alipanah N, et al. Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of Drug-Susceptible Tuberculosis. Clin Infect Dis. 2016;63(7):e147–e195.

Rifapentine (RPT) is also a rifamycin, but with a half-life 5 times longer than RIF, allowing the drug to be given once weekly. The prolonged half-life makes RPT an attractive agent for use in intermittent treatment regimens in order to facilitate adherence.[163] However, use of weekly dosed RPT is associated with relapse and acquired resistance in those with extensive disease, slow sputum culture conversion, or HIV coinfection.[163–165] RPT strongly induces CYP450 leading to multiple potential drug–drug interactions. Other rifamycins (e.g., rifabutin) produce lower levels of CYP450 induction. RPT is generally well tolerated, but hypersensitivity syndromes

TABLE 130-8 TB Drug Dosing and Important Adverse Reactions, Adults

Drug[a]	Daily Dose (Typical Dose)	Intermittent Dose (Typical Dose)	Selected Adverse Events
Isoniazid (INH)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	Hepatotoxicity Peripheral neuropathy
Rifampin (RIF)	10 mg/kg (600 mg)[b]	10 mg/kg (600 mg)[b]	Thrombocytopenia Hepatotoxicity, often hyperbilirubinemia Drug–drug interactions[c]
Rifapentine (RPT)	—	10–20 mg/kg	Drug–drug interactions
Pyrazinamide[d] (PZA)	[e]40–55 kg: 1000 mg 56–75 kg: 1500 mg 76–90 kg: 2000 mg	Varies by weight and dosing interval	Hepatotoxicity Hyperuricemia Arthralgia
Ethambutol[d] (EMB)	[e]40–55 kg: 800 mg 56–75 kg: 1200 mg 76–90 kg: 1600 mg	Varies by weight and dosing interval	Optic neuritis
Moxifloxacin or levofloxacin[d]	400 mg 750–1000 mg	No data to support	GI upset QT prolongation Insomnia Tendinopathy

[a] *All drugs are provided orally; however, INH, RIF, and the fluoroquinolones are available as intravenous formulations.*

[b] *Higher doses of rifampin are well tolerated and associated with higher drug concentrations. However, effect on efficacy needs to be studied.*

[c] *Drug–drug interactions mediated mostly through cytochrome p450–3a4 enzyme induction.*

[d] *May require renal adjustment.*

[e] *Based on estimated lean body weight. Optimal dosing for obese patients is not established.*

Data from Nahid P, Dorman SE, Alipanah N, et al. Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of Drug-Susceptible Tuberculosis. Clin Infect Dis. 2016;63(7):e147–e195.

including fever, myalgia, and cytopenias occurred in about 3% of patients in a clinical trial of LTBI treatment.[166]

PZA is bactericidal and when added to treatment regimens containing RIF permits shortening duration to 6 months.[167] Arthralgias are the most frequently reported adverse event and can be alleviated by the administration of nonsteroidal anti-inflammatories. PZA can also cause severe hepatotoxicity, especially in the elderly and those with pre-existing liver disease.

EMB is the weakest first-line agent, contributing little to early bactericidal activity or to relapse prevention. However, it is effective in preventing the emergence of resistance to isoniazid. It is generally well tolerated. Optic neuritis, the main adverse drug event, occurs infrequently with the currently recommended dosages, but is seen at higher rates with renal impairment. Clinicians should monitor for development of red–green color blindness; some use the Ishihara templates for testing in clinic and/or refer to ophthalmology for periodic monitoring while on treatment. EMB is added to the initial phase of treatment regimens pending results of susceptibility testing; if there is no drug resistance to one of the first-line agents, EMB is then discontinued.[156]

Later-generation fluoroquinolones (FQs), such as moxifloxacin and levofloxacin, are well-tolerated oral drugs with potent bactericidal activity against MTBC.[168–172] Based on accumulating clinical evidence, FQs may enter first-line treatment regimens and may allow for shorter-course regimens.[155] FQs are currently reserved for cases of resistance or intolerance to other first-line drugs.[173]

Pulmonary TB can initially be misdiagnosed as CAP and treated with FQs alone.[174] FQ monotherapy can temporarily alleviate TB symptoms and can reduce the yield of TB sputum cultures, thus significantly contributing to diagnostic delay.[175] Inadvertent monotherapy of TB initially mistaken for CAP also risks the development of FQ resistance, potentially compromising future TB treatment options.[174] FQs should be used cautiously for suspected CAP in patients at significant epidemiologic risk for TB.

■ Adjunctive Corticosteroid Use

Treatment of TB is occasionally complicated by paradoxical treatment responses whereby clinical deterioration develops a few weeks into an otherwise effective treatment.[176,177] The response is characterized by a robust inflammatory reaction, typically at the site of initial disease, without apparent microbiologic failure or bacillary replication. The paradoxical response is most commonly observed in extrapulmonary disease such as scrofula, TB in neck lymph nodes.[178] Paradoxical responses are typically self-limited, even when TB treatment is continued. Symptomatic benefit is sometimes observed following a brief course of corticosteroid treatment.[177] Important differential diagnostic considerations of paradoxical responses that should be excluded prior to treatment with corticosteroids include treatment nonadherence, inadequate dosing, drug malabsorption, or drug-resistant TB.

For disease of the CNS and pericardium, the consequences of a paradoxical response are potentially life threatening, including increased intracranial pressure and constrictive pericarditis, respectively. Meta-analyses have suggested an appreciable benefit to simultaneous initiation of corticosteroids along with TB treatment for these forms of TB.[179–182] The regimens tested in the clinical trials varied but 40 to 80 mg of prednisone per day for 6 to 12 weeks is a common prescription.

■ Direct Observation of Therapy

Direct observation of therapy (DOT) supports adherence, thus improving treatment outcomes.[183] Because physicians are poor at predicting which patients will adhere to therapy, DOT is recommended for all patients.[184]

■ Intermittent Dosing

Direct supervision of therapy by healthcare workers is facilitated by intermittent treatment regimens (e.g., 5 days per week, or Monday–Wednesday–Friday, or even twice weekly). Intermittent dosing schedules take advantage of the slow growth of MTBC and the post-antibiotic effect of TB drugs.[185,186] However, acquired drug resistance has been documented with intermittent dosing schedules, especially in patients with extensive disease or poorly controlled HIV coinfection, and many are moving away from this approach.

■ Treatment Monitoring

Bacteriologic monitoring (e.g., monthly sputum cultures until negative) is the preferred method of follow-up for pulmonary TB cases. A persistently positive sputum culture 2 months after starting effective treatment is a marker for relapse, and treatment extension is suggested. Culture positivity at 3 months is highly suggestive of treatment failure, and patients must be carefully evaluated to identify potential causes (e.g., nonadherence, malabsorption, acquired resistance, poor drug quality, drug–drug interactions). Patients should have repeat drug susceptibility testing and drug levels checked, especially for isoniazid and rifampin. Treatment failure is defined as persistently positive cultures 4 months into treatment.[156]

■ Adverse Effects

Severe side effects necessitating drug discontinuation are rare with standard TB treatment regimens. A commonly encountered adverse event is drug-related hepatotoxicity.[158,187] Transient, mild elevation in liver enzymes early in the course of therapy occurs in about 20% of patients and is usually inconsequential, usually resolving without intervention and without treatment interruption. However, for patients with symptomatic and/or marked elevation of transaminases (above 3–5× the upper limit of normal), treatment should be immediately discontinued and drugs cautiously reintroduced one at a time under close monitoring once the liver enzymes and function have returned to normal.

■ Drug-resistant TB

Among cases in the United States in 2019, resistance to isoniazid occurred in 9.5% of cases.[43] Monoresistance to INH does not appear to compromise TB treatment outcomes substantially as long as RIF, EMB, and PZA can be continued throughout.[156,188–190] It is also recommended to add a later-generation fluoroquinolone for optimal treatment success.[191]

Multidrug resistance was demonstrated in 1.5% of all TB cases in the United States in 2019.[43] Among patients with a history of previous TB treatment, MDR-TB prevalence was 5.4%. The majority (~86%) of MDR-TB cases in the United States occur in non-U.S.-born individuals.

Compared with treatment of drug-susceptible TB, treatment of MDR-TB is challenging, requiring more medications, worse side effects, and longer durations of treatment. Current U.S. and European guidelines recommend using at least five active drugs in the intensive phase, and four drugs in the continuation phase. The recommended treatment duration is 15 to 21 months after culture conversion. Drug classes used in the treatment of drug-resistant tuberculosis include fluoroquinolones, bedaquiline, linezolid, cycloserine, clofazimine, and injectable aminoglycosides now as a last resort.[191] Trials of shorter-course regimens of 9 to 12 months have had positive results,[29,192–195] including an all-oral bedaquiline-containing regimen that is now recommended by the WHO for certain patients.[32] These shorter-course regimens are not yet recommended by U.S. guidelines. Second-line TB agents and important side effects are listed in Tables 130-9 and 130-10.

TABLE 130-9 U.S./European Guidelines for Second-line TB Drugs

Group	Drugs
Strongly recommend use	Bedaquiline, fluoroquinolone (moxifloxacin or levofloxacin)
Conditionally recommend use	Linezolid, clofazimine, cycloserine, injectable amikacin, injectable streptomycin, ethambutol, pyrazinamide, injectable carbapenems w/clavulanic acid, delamanid
Conditionally recommend *against* use	Ethionamide prothionamide, injectable kanamycin, p-aminosalicylic acid, injectable capreomycin
Strongly recommend *against* use	Macrolides (azithromycin, clarithromycin), amoxicillin/clavulanate

Choice of medications further guided by prior treatment history and drug susceptibility testing.

U.S./European guideline recommends using at least five drugs in intensive phase (5–7 months after culture conversion) and four drugs in the continuation phase (15–21 months, longer if pre-XDR-TB or XDR-TB). Do not yet recommend for or against short-course 9- to 12-month regimen endorsed by World Health Organization.

Data from Nahid P, Mase SR, Migliori GB, et al. Treatment of Drug-Resistant Tuberculosis. An Official ATS/CDC/ERS/IDSA Clinical Practice Guideline. Am J Respir Crit Care Med. 2019;200(10):e93–e142.

TABLE 130-10 Second-line TB Drugs and Selected Toxicities

Agent	Important Adverse Effects
Amikacin (and other aminoglycosides)	Hearing loss, renal failure
Bedaquiline	QT prolongation, hepatotoxicity
Clofazimine	Skin hyperpigmentation, moderate QT prolongation
Cycloserine	Psychosis, depression, anxiety, seizures
Delamanid	Mild QT prolongation
Ethambutol	Optic neuropathy
Ethionamide/ prothionamide	Nausea, vomiting, hypothyroidism
Imipenem/clavulanic acid	Seizures, rash
Levofloxacin	QT prolongation, tendinitis, Achilles tendon rupture
Linezolid	Bone marrow suppression, peripheral neuropathy, optic neuritis
Meropenem/ clavulanic acid	Rash
Moxifloxacin	QT prolongation, tendinitis, Achilles tendon rupture
P-aminosalicylic acid	Nausea, vomiting, diarrhea, hypothyroidism
Pyrazinamide	Hepatotoxicity[a]

[a] *Risk factors for pyrazinamide hepatotoxicity include advanced age and underlying liver disease.*

■ Treatment Issues in Special Populations

Treatment considerations in two special patient populations—those coinfected with HIV and solid organ transplant recipients—are discussed below.

HIV Coinfection

Standard regimens used for the treatment of TB in HIV-uninfected individuals have similar efficacy in HIV-infected individuals, provided these patients are also effectively treated with antiretroviral therapy (ART).[196] However, the addition of ART to TB treatment can result in overlapping drug toxicity and intolerances including peripheral neuropathy, hepatotoxicity, and GI upset. Potent bidirectional drug–drug interactions between rifampin and several classes of antiretroviral drugs can amplify toxicity and undermine HIV virologic control. A number of studies have also found reduced serum concentrations of TB drugs in patients coinfected with HIV, thought to be due to decreased gastrointestinal absorption.[197] In turn, low serum drug concentrations may increase the risk of treatment relapse or acquired rifamycin resistance. Intermittent RPT in the continuation phase is associated with higher relapse rates and acquired rifamycin resistance in HIV-infected individuals and should be avoided.[163,165,198]

Successful HIV treatment with ART can lead to immune reconstitution and, in patients with concurrent active TB, restores the host inflammatory response to TB infection. This can clinically present as transient worsening of TB disease a few weeks following initiation of ART (a phenomenon known as immune reconstitution inflammatory syndrome or TB-IRIS). TB-IRIS can occur following ART initiation in patients already on treatment for TB (paradoxical type) or in patients with previously undiagnosed TB (unmasking type). TB-IRIS produces significant morbidity, occasionally requiring glucocorticoid therapy for symptom control.[199] However, in patients diagnosed simultaneously with HIV and TB, treatment outcomes, relapse rates, and overall mortality are greatly improved when ART is added early, within a few weeks of initiating TB treatment, even if this strategy noticeably increases risk of TB-IRIS.[156,200,201] An exception to this is for CNS TB, for which it is recommended that ART initiation be delayed by 8 weeks.[156,202] A short course of oral prednisone at the time of ART initiation in patients with HIV/TB coinfection and advanced HIV disease decreases the risk for TB-associated IRIS without increasing risk of death or complications.[203]

Solid-organ Transplantation

The majority of TB cases in solid-organ transplant recipients arise from reactivation of latent infection acquired prior to transplantation.[204] Donor-derived TB transmitted with organ transplantation is very rare. Overlapping drug toxicity and significant drug–drug interactions complicate treatment of TB in transplant recipients.[205] RIF significantly lowers serum drug concentrations of immunosuppressant medications, which can precipitate organ rejection. Rifabutin, a rifamycin with less CYP450 activity than either RIF or RPT, has good activity against MTBC and can be used instead of RIF in standard TB regimens.[206–208] Liver transplant recipients are particularly prone to hepatotoxicity from isoniazid, rifampin, and pyrazinamide, and close monitoring of liver function tests is indicated.[208]

TARGETED TESTING AND TREATMENT OF LATENT TB INFECTION

The use of anti-TB drugs in latently infected patients to prevent subsequent progression to active disease was first reported in the early 1950s.[209] Dozens of controlled clinical trials subsequently confirmed that INH reduced the risk of TB in those with positive TST by 60% to 90%, depending on the level of adherence.[210–212] An estimated 4% of the U.S. population is latently infected,[213] but currently available tests do not reliably predict which infected individuals will eventually develop active disease.[214] Furthermore, up to 5% of those treated for latent infection will experience an adverse event; rarely this can be severe hepatotoxicity and fulminant hepatic failure.[158,215,216] Thus, the decision to treat LTBI must be individualized, balancing the risk of developing active TB against the potential for adverse events.

Diagnosis of LTBI

The diagnosis of latent TB infection hinges on a positive TST and/or IGRA (discussed above). Once infected with MTBC, it is believed that the potential for reactivation persists for the lifespan of the host.

Tuberculin Skin Test

The TST is more than 100 years old.[217] The most commonly used method for administering the TST is the Mantoux technique: Here, five tuberculin units of purified protein derivative (PPD) from *M. tuberculosis* are injected intradermally on the inner surface of the left forearm. In those individuals with cell-mediated immunity to PPD, a delayed-type hypersensitivity (DTH) response will occur, manifest as a circular indurated skin reaction arising at the site of injection 48 to 72 h later.

Several factors can undermine the predictive value of the TST for latent TB infection.[143] Potential causes of false-negative reactions include immune compromise, malnutrition, chronic renal failure, improper administration, and expiration of tuberculin.[216,217] TB disease itself reduces test sensitivity, with up to 25% of TB cases TST negative. The TST is also prone to false-positive reactions. PPD is a relatively crude extract of mycobacterial antigens, many of which are conserved between mycobacterial species. Sensitization to PPD can develop after routine exposure to environmental NTM or following previous vaccination with BCG.[143]

Although technically simple, significant training and expertise is required for reliable test performance and interpretation. Roughly speaking, the larger the reaction size, the more likely is latent TB infection. The predictive value of the test varies by prevalence of LTBI and immunocompetence, and different reaction size criteria are used to define positivity in different populations[146,216] (Table 130-11).

Interferon-γ Release Assays

IGRAs are in vitro blood tests of CMI response; they measure T-cell release of IFN-γ following stimulation by synthetic peptide antigens specific to *M. tuberculosis*.

Replacing the mixture of antigens contained in PPD with specific synthetic peptides greatly improves the specificity of IGRAs compared to TST, especially in populations previously vaccinated with BCG.[218,219] The sensitivity of the IGRA is comparable to the TST, even in immunocompromised hosts, although the absence of a gold standard makes precise estimation difficult.[220–222]

IGRA appear less reproducible on repeated testing than is TST, especially when values of IFN-γ release are near the quantitative threshold for reporting positive (i.e., borderline positive).[212] This can result in spontaneous conversions and reversion on serial testing of the same individual, with uncertain clinical implications.[223]

There are two currently approved IGRA tests available in the United States: the QuantiFERON-TB Gold and QuantiFERON-TB Gold Plus assays (Qiagen, Gaithersburg, Maryland) and the T-SPOT.TB assay (Oxford Immunotec, United Kingdom).

Which Test to Use in LTBI

Either the TST or the IGRA are acceptable for the diagnosis of LTBI.[145,146] The improved specificity of IGRAs and the need for a single patient visit make this test attractive. IGRAs are associated with high testing costs and require laboratory infrastructure and significant technical expertise. The improved specificity of the IGRA might reduce the number of candidates for LTBI treatment,

TABLE 130-11 Considerations for Testing for Latent Tuberculosis Infection, Adults

Group	Testing Strategy	Considerations
Likely[a] to be infected **High**[b] risk of progression (TST ≥5 mM)	**Acceptable**: IGRA or TST Consider dual testing where a positive result from either would be considered **positive**	Prevalence of BCG vaccination Expertise of staff and/or laboratory Test availability Patient perceptions Staff perceptions Programmatic concerns
Likely to be infected **Low to intermediate**[c] risk of progression (TST ≥10 mM)	**Preferred**: IGRA where available **Acceptable**: IGRA or TST	
Unlikely to be infected (TST >15 mM)	**Testing for LTBI is not recommended** **If necessary:** **Preferred:** IGRA where available **Acceptable:** IGRA or TST **For serial testing:** **Acceptable**: IGRA or TST Consider repeat or dual testing where a negative result from either would be considered positive.	

LTBI, latent tuberculosis infection; TST, tuberculin skin test; IGRA, interferon-gamma release assay; BCG, bacille Calmette-Guérin.

[a] *Groups with increased likelihood of infection: household contact or exposure of active case, mycobacteriology laboratory personnel, immigrants from high-burden countries (>20/100,000), residents and employees of high-risk congregate settings.*

[b] *Factors conferring high risk of progression: age <5 years old, HIV infection, immunosuppressive therapy, abnormal chest x-ray consistent with prior TB, silicosis.*

[c] *Factors conferring intermediate risk of progression: diabetes, chronic renal failure, intravenous drug use.*

Data from Lewinsohn DM, Leonard MK, LoBue PA, et al. Official American Thoracic Society/Infectious Diseases Society of America/Centers for Disease Control and Prevention Clinical Practice Guidelines: Diagnosis of Tuberculosis in Adults and Children. Clin Infect Dis. 2017;64(2):e1–e33.

but whether this translates to cost-effectiveness is controversial.[224] The choice of whether to use TST, IGRA, or both is dependent on the pretest probability of infection (based on risk factors), and the risk of progression to active TB (based on immune suppression and comorbidities).[146]

■ Decision to Treat LTBI

The first step in deciding whether to treat for LTBI is to assess the likelihood that a positive TST or IGRA represents true TB infection. Both tests perform poorly in low-prevalence populations, and a true positive result is much more likely in those exposed to active TB or from high-risk epidemiologic groups such as foreign-born, travelers to TB endemic countries, homeless, and incarcerated populations.

The second step is to estimate likelihood of progression to active TB if actually infected[221] (Table 130–2). The third step is to evaluate potential risks for adverse reactions to treatment. The main adverse effect of LTBI treatment is INH-related hepatotoxicity. The strongest predictor of hepatotoxicity is age. Those younger than 20 years old have less than a 0.1% chance of hepatotoxicity during LTBI treatment, whereas those over 65 years are exposed to a risk around 2% to 5%. An internet-based calculator is available to assist in balancing these probabilities and informing treatment decisions.[225] However, this calculator does not take into account reinfection, and the toxicity is calibrated for INH rather than the newer rifamycin-based regimens.

Treatment of LTBI has been demonstrated to be effective only in those with a positive TST or IGRA. Several clinical trials have failed to demonstrate a benefit of treatment in immunocompromised individuals at risk but with a negative TST or IGRA.[226,227]

Before the treatment of LTBI is started, active disease must be excluded carefully by means of history, physical examination, chest radiography, and sputum culture, in order to avoid inadvertent monotherapy of active TB that could lead to resistance.

■ Treatment for LTBI

Historically, the most widely used treatment of LTBI is self-administered INH taken daily for 9 months.[212,228] However, increasing evidence has led to a shift in guidelines to now recommend rifamycin-based regimens over INH monotherapy. The three preferred rifamycin-based regimens include 3 months of weekly isoniazid plus rifapentine, 3 months of daily isoniazid plus rifampin, or 4 months or daily rifampin monotherapy.[229] Preferred and alternative regimens are shown in Table 130-12. Contacts of INH-monoresistant cases can be offered 4 months of RIF daily. Contacts of MDR-TB can be offered therapy with 6 to 12 months of a daily later-generation FQ, with or without an additional drug. This recommendation is based on observational studies, although randomized trials are underway.[191]

Patients receiving LTBI treatment should be monitored at least monthly for clinical symptoms of hepatitis. They should also be educated about the symptoms of hepatitis and instructed to stop the medication immediately and seek prompt evaluation to reduce risk for progression to severe disease.

TABLE 130-12 Preferred and Alternative Regimens for Treatment of Latent Tuberculosis Infection, Adults

Priority Rank	Duration	Frequency	Drugs
Preferred	3 months	Weekly[b]	Isoniazid[a]: 15 mg/kg (max 900 mg) + Rifapentine: if $\geq$ 50 kg[c], 900 mg
Preferred	4 months	Daily	Rifampin: 10 mg/kg
Preferred	3 months	Daily	Isoniazid[a]: 5 mg/kg (max 300 mg) + Rifampin: 10 mg/kg (max 600 mg)
Alternative	6 months	Daily	Isoniazid[a]: 5 mg/kg (max 900 mg)
Alternative	9 months	Daily	Isoniazid[a]: 5 mg/kg (max 900 mg)

[a] *Pyridoxine supplementation (25–50 mg daily) often provided to prevent INH-associated peripheral neuropathy, especially if risk factors including alcohol use disorder, diabetes, malnutrition, uremia, and HIV infection.*

[b] *Intermittent regimens should be provided under direct observation.*

[c] *Rifapentine dosing for lower weight: 10–14.0 kg (300 mg), 14.1–25.0 kg (450 mg); 25.1–32.0 kg (600 mg); 32.1–49.9 kg (750 mg).*

TB VACCINATION

French researchers Albert Calmette and Camille Guérin experimented with laboratory attenuation of *M. bovis* by repeated subcultivations in bile acids; this work eventually led to the creation of a TB live-attenuated vaccine BCG in 1928.[230,231] This vaccine is rarely used in the United States today, but worldwide it remains one of the most commonly delivered childhood vaccines with coverage rates approaching 100% in many resource-limited settings. Despite its wide use, there remains some controversy as to its actual efficacy, and some concern that ongoing subculture to produce the vaccine is resulting in loss of activity.[232] Disseminated infection with BCG has been documented in severely immunocompromised children, and universal vaccination is therefore no longer recommended in low-prevalence settings.[233] In the Unites States, BCG is perhaps more commonly encountered as a therapeutic agent for management of bladder transitional cell carcinoma. Disseminated BCG infection has been documented in this patient group, but human-to-human transmission is not reported.[234,235]

Ongoing research is directed toward a vaccine to replace BCG, ideally with improved efficacy against both infection and progression to TB.[236] However, after millennia of coevolution, the host–pathogen relationship is extremely complex and inadequate understanding of TB immunity and correlates of protection hamper progress in vaccine development.

CONCLUSION

TB has become an uncommon but serious infection in the United States, and a high index of suspicion is required. In endemic regions, clinicians tend to consider the diagnosis more frequently. Diagnostic delay occurs frequently despite availability of accurate diagnostic technologies. In settings of chronic medical illness, immunocompromise, and social deprivation, TB can flourish. Treatment is effective and can significantly reduce a high case-fatality rate. Current research is directed to shortening the duration of therapy to facilitate adherence and treatment completion rates. New drugs are being developed and promise to improve outcomes in MDR disease. Ongoing national surveillance and funding of TB control programs is required to maintain low TB incidence. However, given that an increasing proportion of TB relates to global migration, further reduction in TB incidence will ultimately require investment in TB control globally. Even in the wealthy countries of the West, TB is not conquered but continues to smolder, threatening reemergence where social injustice prevails and where the vigilance of TB control programs is relaxed.

CHAPTER 131

Pulmonary Diseases Due to Nontuberculous Mycobacteria

John S. Albin
Rocio M. Hurtado

INTRODUCTION

This chapter focuses on the diagnosis and management of pulmonary infections caused by nontuberculous mycobacteria (NTM), a large group of species of the genus *Mycobacterium* that can cause disease in humans and that are distinct from other classic mycobacterial pathogens, such as *M. leprae*, *M. ulcerans*, and species of the *M. tuberculosis* complex. Despite the diversity of this group of pathogens, the clinical presentation and diagnostic approach to most pulmonary NTM infections is similar, and the vast majority of disease is caused by a handful of species, including those of the *M. avium* (MAC) and *M. abscessus* (MAb) complexes, as well as *M. kansasii* and *M. xenopi*. Management differs according to species, extent of disease, and susceptibility patterns. We describe here the epidemiology and pathogenesis of pulmonary NTM infections and a general diagnostic approach. We then proceed to the treatment regimens used for common NTMs and discuss the nuances associated with management in special populations.

EPIDEMIOLOGY

There are 192 known species of the genus *Mycobacterium*.[1] Of these, several are *M. tuberculosis* complex species that cause tuberculosis in humans, while *M. leprae* causes leprosy and *M. ulcerans* causes Buruli ulcer. Most of the remainder are known as nontuberculous mycobacteria (NTM), which are environmental organisms typically found in soil and water. Together, they constitute the greatest source of pulmonary mycobacterial infection in developed nations. Most human pulmonary NTM disease is caused by species of the *M. avium* and *M. abscessus* complexes, as well as *M. kansasii* and *M. xenopi*; others, such as *M. gordonae*, are generally considered contaminants.[2] The relative contributions of each species responsible for infection may vary geographically.[3–5] Overall, prevalence has increased by up to 8.2% per year in recent decades, representing up to 48 cases per 100,000 in the United States as of 2012.[2,6]

Among risk factors for pulmonary NTM disease that predispose to infection, a common theme is underlying structural lung abnormalities that impede physiologic airway clearance or ciliary function. Notable among these underlying diagnoses are bronchiectasis, chronic obstructive pulmonary disease, pneumoconiosis, and pulmonary alveolar proteinosis. Cystic fibrosis, including the presence of cystic fibrosis transmembrane conductance regulator (CFTR) changes not associated with clinical cystic fibrosis, and α1-antitrypsin deficiency are two genetic conditions that predispose to pulmonary NTM infection.[7,8] Additional associations that have been observed are listed in Table 131-1. Although immunodeficiency is a risk factor for both pulmonary and disseminated NTM infections,[9] the vast majority of pulmonary NTM infection occurs in the absence of known immunodeficiency.

PATHOGENESIS

Abnormal airway clearance allows persistence of pulmonary NTMs that would otherwise normally be cleared. Distinguishing colonization from infection can be challenging, as more than half of patients may undergo spontaneous sputum conversion from positive to negative.[10,11] Once infection is established, pulmonary NTMs can persist within biofilms and macrophages, which may shield NTMs from antibiotic therapy.[12–16] Absent clearance, the natural history of disease is generally one of slowly progressive lung destruction over a course of years, although this course may wax and wane. Treatment success is limited, but even those who achieve sputum conversion remain susceptible to reinfection due to persistence of the abnormalities that predisposed to initial infection.[4]

DIAGNOSIS

The diagnosis of pulmonary NTM infection is based on clinical and radiographic findings, along with appropriate microbiology, in the absence of an alternative diagnosis. Guidelines have been developed to help facilitate interpretation of what can sometimes be diagnostically challenging cases (Table 131-2). Symptoms often include cough (74%–82%), dyspnea (47%–55%), hemoptysis (10%–27%), fever (24%–38%), weight loss (5%–32%), and fatigue or malaise (53%–66%).[4,5,17] A variety of imaging findings may be seen on CT, and certain patterns, such as nodular bronchiectatic or fibrocavitary changes, which may wax and wane over time, may help guide treatment.[4,8,18] Examples of several commonly encountered radiographic findings are shown in Fig. 131-1.

The microbiologic diagnosis of pulmonary NTM infection can be made by several means, including, most commonly, growth of the same NTM species in two or more sputum samples (Table 131-2).[18] Criteria may also be fulfilled by NTM growth from a single bronchoalveolar lavage sample, or the observation of typical lung pathology on biopsy, such as granulomatous inflammation or the finding of

TABLE 131-1 Common Risk Factors and Associations with Pulmonary NTM Infection

Structural Lung Abnormalities	Genetic Predispositions	Other Associations
• Bronchiectasis due to any cause (e.g., sequela of infection such as tuberculosis) • Chronic obstructive pulmonary disease • Pulmonary alveolar proteinosis • Pneumoconiosis	• CFTR changes including cystic fibrosis • α1-antitrypsin deficiency • Rare genetic variants associated with family clusters	• Gastroesophageal reflux, esophageal dysmotility • Older age • Lower BMI • Female sex • Immunosuppression • Scoliosis, pectus excavatum • Mitral valve prolapse

TABLE 131-2 Criteria for the Diagnosis of Pulmonary NTM Disease[a]

Category	Conditions to Fulfill Criteria (Must Fulfill All Three Categories)
Clinical	• Pulmonary or systemic symptoms
Radiologic	• Nodular or cavitary opacities, bronchiectasis on chest imaging
Microbiologic	• ≥2 positive sputum cultures with the same NTM species *or* • ≥1 positive bronchoalveolar lavage culture growing NTMs *or* • Lung biopsy with characteristic pathology (granulomatous inflammation or acid fast bacilli) *and* • Biopsy culture growing NTMs *or* • ≥1 or more respiratory cultures growing NTMs

[a]Data from American Thoracic Society (ATS), European Respiratory Society (ERS), European Society of Clinical Microbiology and Infectious Diseases (ESCMID), and Infectious Diseases Society of America (IDSA) guidelines for the treatment of pulmonary NTM infections.

acid-fast bacilli accompanied by NTM growth from the biopsy sample itself or from an accompanying respiratory sample. Rapidly growing mycobacteria, such as MAb, *M. chelonae*, and *M. fortuitum*, may grow in as little as 1 week, while slowly growing mycobacteria (most of the remaining species) may require several weeks or more. Most species will grow within 8 weeks—the typical duration for which cultures are held, although certain species, such as *M. xenopi*, may take longer. Others, such as *M. haemophilum*, have specific nutrient and temperature requirements. Identification may proceed via use of rapid nucleic acid probes for some species, such as *M. kansasii*, MAC, and the common low-virulence species *M. gordonae*. Definitive identification is typically based on gene sequencing or mass spectrometry, although the latter may fail to distinguish some subspecies. PCR on fresh tissue also may be used.

In vitro susceptibility to certain agents strongly predicts clinical outcomes. Current recommendations are to test for MAC and MAb susceptibility to macrolides and amikacin. In the case of MAb, molecular methods or a 14-day hold for culture may further be necessary to evaluate for an inducible *erm* gene conferring macrolide resistance. Guidelines also support testing of *M. kansasii* for susceptibility to rifampin.[18] Standard susceptibilities may be completed in many laboratories, albeit with some variability in reproducibility;[19] extended susceptibilities may require send out to reference laboratories.

TREATMENT

Among patients with positive cultures, 14% to 43% will fulfill guideline diagnostic criteria for pulmonary NTM infection.[4,5,17] Even among patients meeting criteria, the decision to treat is nuanced and based on a longitudinal assessment of expected risks and benefits of treatment, including comorbidities, life expectancy, drug interactions and adverse effects, and the functional impact of disease progression. More than half of patients with MAC may experience progressive disease over a course of 3 years, leading to treatment.[10]

Up to one-third of patients with MAC may receive suboptimal regimens associated with emergent macrolide resistance, such as macrolide monotherapy or dual therapy consisting of a macrolide and either a fluoroquinolone or a rifamycin.[20] Therapy is further complicated by the frequency of subtherapeutic drug levels, which may be mitigated by therapeutic drug level monitoring.[21] The overall proportion of patients who improve on therapy varies by the infecting species but, overall, is about two-thirds; adverse events occur in more than one-third. Cessation of therapy is required in approximately 14%, and microbiologic recurrence, including reinfection, occurs in 17% to 48%.[4,22,23] Composite 5-year survival has been reported at 73%.[24]

Side-effects from treatment are common, particularly gastrointestinal intolerance, occurring in more than 40%.[25] Despite limitations of therapy, patients with pulmonary NTM infections suffer from diminished quality of life and may benefit from treatment, which is intended to prevent decline in lung function.[26–29] Common treatment regimens are summarized in Table 131-3. Major toxicities associated with treatment are summarized in Table 131-4 and discussed below.

■ *Mycobacterium avium* Complex (MAC)

MAC refers to a group of 12 species that are the most commonly encountered pulmonary NTM pathogens in the United States.[18] The initial therapeutic regimen used in most cases consists of the trio of a macrolide (azithromycin is preferred over clarithromycin,

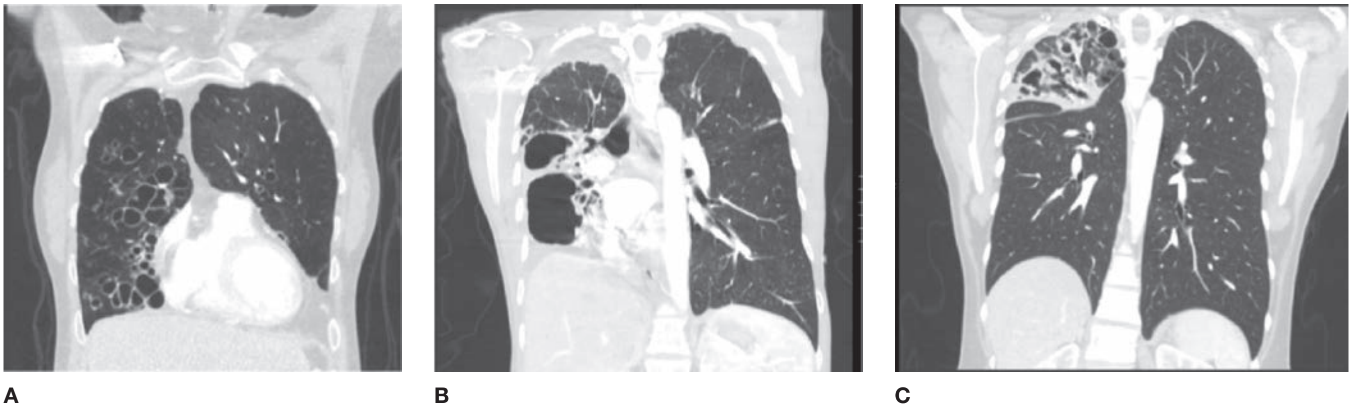

Figure 131-1 Radiographic findings in pulmonary NTM infections. Images demonstrate several radiographic patterns observed among patients with pulmonary NTM infections. **A.** Cystic bronchiectasis in a patient with cystic fibrosis and *M. kansasii* infection. **B.** Fibrocavitary disease in a patient with MAC, in this case complicated by bronchopleural fistula. **C.** Progressive right upper lobe bronchiectasis and cavitation with *M. tuberculosis* and *M. chelonae* coinfection in a patient who went on to have surgical resection.

TABLE 131-3 Preferred Treatment Regimens with Normal Renal Function[a]

NTM (Susceptibility Duration)	Disease Category	Dosing Regimen (Minimum of Three Drugs)
MAC Test: • Macrolides • Amikacin Duration: • 12 months after sputum conversion (minimum)	Nodular-bronchiectatic	Dosed thrice weekly • Ethambutol 25 mg/kg po • Rifampin 600 mg po[b] • Azithromycin 500 mg po[b]
	Cavitary, extensive, or macrolide-resistant	Dosed daily • Ethambutol 15 mg/kg po • Rifampin 450–600 mg (10 mg/kg) po[b] • Azithromycin 250–500 mg po[b] Dosed thrice weekly • Amikacin 15–25 mg/kg[b]
	Refractory	Dosed daily • Ethambutol 15 mg/kg po • Rifampin 450–600 mg (10 mg/kg) po[b] • Azithromycin 250–500 mg po[b] ***and*** • ALIS 590 mg inhaled *daily* ***or*** • Amikacin 15–25 mg/kg *thrice weekly*[b]
MAb Test: • Macrolides • Amikacin • A broader panel of potentially active agents Duration: • Variable; options include induction of several months followed by oral maintenance for 12 months after sputum conversion (minimum) versus intermittent induction	Macrolide-sensitive	Initial therapy (1–2 IV, 2 oral, ≥3 active drugs) *IV:* Amikacin 15–25 mg/kg IV thrice weekly Imipenem 500–1000 mg IV 2–3 times daily[d] Cefoxitin 2–4 g IV 3 times daily[d] Tigecycline 25–50 mg IV 1–2 times daily[e] *Oral:* Azithromycin 250–500 mg daily[b] Clofazimine 100–200 mg daily Linezolid 600 mg 1–2 times daily[e] Continuation phase (≥2 active drugs) Oral agents as above ALIS 590 mg daily inhaled
	Macrolide-resistant	Initial therapy (2–3 IV, 2–3 oral, ≥4 active drugs) *IV:* As in macrolide-sensitive strains *Oral:* As in macrolide-sensitive strains[f] Continuation phase (≥2 active drugs total) Oral agents as above[f] ALIS 590 mg daily inhaled
M. kansasii Test: • Rifampin Duration: • 12 months	All categories	Dosed daily[c] • Ethambutol 15 mg/kg po • Rifampin 450–600 mg (10 mg/kg) po[b] ***and*** • Azithromycin 250–500 mg po[b] ***or*** • Isoniazid 5 mg/kg (up to 300 mg) po[b]
M. xenopi Test: • No standard Duration: • 12 months after sputum conversion (minimum)	Nodular-bronchiectatic	Dosed daily • Ethambutol 15 mg/kg po • Rifampin 450–600 mg (10 mg/kg) po[b] ***and*** • Azithromycin 250–500 mg po[b] ***or*** • Moxifloxacin 400 mg po

TABLE 131-3 Preferred Treatment Regimens with Normal Renal Function[a] *(Continued)*

NTM (Susceptibility Duration)	Disease Category	Dosing Regimen (Minimum of Three Drugs)
	Cavitary or extensive	Dosed daily • Oral agents as in nodular-bronchiectatic ***and*** Dosed thrice weekly Amikacin 15–25 mg/kg IV[b]

[a] *Data from American Thoracic Society (ATS), European Respiratory Society (ERS), European Society of Clinical Microbiology and Infectious Diseases (ESCMID), and Infectious Diseases Society of America (IDSA) guidelines for the treatment of pulmonary NTM infections. Dosing is adapted from guideline recommendations for normal renal function, although it is important to keep in mind that additional factors such as renal function and MICs (from susceptibility testing) may mandate different dosing or alterations in regimen. Consultation with pharmacy is recommended throughout, particularly for management of aminoglycosides. In re-treatment patients, patients with macrolide resistance, or patients failing therapy, expert consultation is recommended.*

[b] *Azithromycin, rifampin, or amikacin may be substituted by clarithromycin, rifabutin, or streptomycin, respectively. Please note, some M. xenopi strains may be resistant to rifampin.*

[c] *When a macrolide-based regimen is chosen, dosing may be thrice weekly as in MAC rather than daily.*

[d] *Only one of cefoxitin or imipenem should be used in any given regimen.*

[e] *Daily dosing (50 mg/day) is generally preferred for tolerability.*

[f] *Although a macrolide may be retained in macrolide-resistant infections for other indications such as immunomodulation, this should not be counted against the recommended number of active drugs.*

TABLE 131-4 Major Toxicities Associated with Drugs Commonly Used to Treat NTMs[a]

Drug	Toxicities	Management
ALIS	• Respiratory adverse events	• Symptomatic management of dysphonia, upper irritation; bronchodilators for cough, dyspnea; may be able to reintroduce without symptoms after a drug holiday
Aminoglycosides	• Ototoxicity	• Lower risk with thrice-weekly dosing; audiology every few weeks; cessation of drug if occurs
	• Nephrotoxicity	• Monitor drug levels; drug holiday and change in dosing in consultation with pharmacy
Bedaquiline	• QTc prolongation	• Monitor ECG; minimize QTc prolonging agents
β-lactams	• Cytopenias	• Lab monitoring, cessation if occurs
	• Seizures	• Monitor for symptoms
Clofazimine	• Skin changes	• Counseling for expectation of discoloration and xerosis
	• QTc prolongation	• Monitor ECG; minimize QTc prolonging agents
	• Intussusception	• Counseling to monitor for symptoms
Ethambutol	• Optic neuritis	• Ophthalmology evaluation every few months; cessation of therapy if occurs
Fluoroquinolones	• Tendon rupture	• Counseling to avoid strenuous activity; cessation of therapy if occurs
	• QTc prolongation	• Monitor ECG; minimize QTc prolonging agents
Isoniazid	• Hepatotoxicity	• Symptomatic and lab monitoring; cessation of therapy if occurs
	• Neuropathy	• Coadministration of vitamin B6
Macrolides	• Hearing loss	• Audiology at baseline; monitor symptoms; cessation of therapy if occurs, but may be able to tolerate clarithromycin
	• QTc prolongation	• Monitor ECG; minimize QTc prolonging agents
Oxazolidinones	• Cytopenias	• Lab monitoring; cessation of therapy if occurs; may be able to tolerate tedizolid
	• Drug–drug interactions	• Avoid serotonergic drugs; monitor symptoms[b]
	• Optic neuritis	• Monitor symptoms; cessation if occurs
	• Neuropathy	• Coadministration of vitamin B6
Rifamycins[c]	• Drug–drug interactions	• Avoid use with CYP3A4 substrates[b]
	• Hepatotoxicity	• Symptomatic and lab monitoring; cessation of therapy; if minor, may later be reintroduced
	• Cytopenias	• Cessation of therapy
Tetracyclines	• Gastrointestinal disturbance and granulomatous hepatitis	• Start tigecycline at low dose with slow dose escalation over weeks
	• Pancreatitis	• Add amylase/lipase to usual lab monitoring

[a] *All of the agents discussed in this chapter may contribute to common side effects such as gastrointestinal disturbance, rashes, and abnormalities on liver function testing. This is separately denoted for agents where this is particularly common or severe. In practice, we monitor labs on a monthly basis in uncomplicated oral regimens and weekly on IV regimens. Consultation with pharmacy is generally advisable, particularly for management of aminoglycosides.*

[b] *Details of common drug–drug interactions are discussed in the main text sections on each drug as well as the Special Populations section.*

[c] *Although not a toxicity, patients should be counseled on expected secretion discoloration.*

based on side effects), ethambutol, and a rifamycin (rifampin is preferred over rifabutin).[18,30,31] Injectable agents (e.g., amikacin or streptomycin) are included in regimens for severe, cavitary, or macrolide-resistant disease. Macrolides, particularly azithromycin, carry a low risk of potentially irreversible pan-frequency hearing loss, as well as gastrointestinal side effects and hepatitis.[32] Baseline audiology with repeat testing for symptoms may be helpful. Clarithromycin may be associated with less ototoxicity, but the drug is dosed twice daily and has more drug interactions and gastrointestinal side effects.[33]

In the context of MAC therapy, ethambutol carries a 6% risk of optic neuritis when dosed daily at 15 mg/kg (less when dosed three times weekly at 25 mg/kg); this form of toxicity commonly manifests months into therapy as blurred vision or changes to red–green color vision affecting one or both eyes. In most cases, the findings improve or resolve within several months following cessation of therapy.[34] Baseline ophthalmology examination prior to the start of therapy and every 3 months thereafter, as well as counseling the patient to hold therapy for visual changes pending evaluation, may minimize progression.

Rifampin has a number of potential adverse effects, including gastrointestinal intolerance, hepatotoxicity, and cytopenias. Relevant drug interactions are also important to recognize, including increased metabolism of anticoagulant and immunosuppressive medications via induction of CYP3A4 enzymes, which may necessitate changes in therapy. Rifampin hepatotoxicity occurs in up to 19% of MAC treatment courses. Hepatotoxicity may be monitored when mild; when severe, management centers on cessation and subsequent reintroduction, which can be accomplished in 90% of patients.[33]

Macrolide-resistant MAC portends a long duration of therapy, unfavorable outcome, and high rate of death. Resistance is associated with changes in the 23S rRNA *rrl* gene when a macrolide is used alone, with a quinolone, or without ethambutol.[35] Daily dosing of the oral regimen, along with intensification of the regimen with the addition of 2 to 3 months of an aminoglycoside, is used for severe or cavitary disease, as well as for macrolide resistance.[36] Additional agents, such as clofazimine and bedaquiline, also may be considered.

Use of long-term aminoglycosides may result in irreversible high-frequency ototoxicity, more commonly in older patients and with use of greater cumulative doses; vestibular toxicity and renal toxicity also may be seen. Typical monitoring includes audiology every few weeks, in addition to weekly laboratory tests to assess renal function. For patients who have failed 6 months of therapy, amikacin liposome inhalation suspension (ALIS) may be added to improve rates of culture conversion.

For noncavitary, nonsevere disease, three times weekly, rather than daily, therapy is associated with lower rates of drug regimen changes and similar rates of culture conversion and macrolide resistance.[37] The extent of disease and bacillary burden may be considered as additional factors in determining the need for daily regimens.

The overall rate of culture conversion has been reported at 60% (41%–74%), with 16% stopping therapy prematurely.[32] Recurrence is most commonly due to reinfection with a new strain, although true relapse may be more common among patients who do not complete a full course of therapy.[38] Guidelines recommend at least 12 months of therapy past the date of culture conversion, although this may be extended in selected patients with more severe disease, depending on clinical and radiographic evolution.[18]

■ *Mycobacterium abscessus* Subspecies (MAb)

Pulmonary *M. abscessus* infection refers to infection with any of three subspecies within the *M. abscessus* complex—*M. abscessus*, *M. bolletii*, or *M. massiliense*. The last of these three is distinguished by its nonfunctional *erm* 23S rRNA methylase, which confers inducible macrolide resistance in the former two.[39] Mutations in the 23S rRNA *rrl* gene may contribute to constitutive macrolide resistance, while 5% of isolates carry 16S rRNA *rrs* mutations that may contribute to amikacin resistance.[40] MAb as a whole are the most resistant NTMs, and outcomes are often suboptimal in the absence of surgical resection of diseased lung.[41] Cure rates approximate 50%, with 20% recurrence and lower success rates in patients with recurrent disease, or in those whose disease is due to macrolide-resistant MAb; macrolide-sensitive *M. massiliense* is more responsive to treatment.[42]

For patients with susceptible isolates, guidelines support inclusion of a macrolide in a regimen consisting of at least three active drugs.[18] A common therapeutic approach is to complete an induction course of up to several months, during which at least one oral agent and two parenteral agents (amikacin, tigecycline, and either cefoxitin or imipenem) are administered. One reported series noted the highest success rates with amikacin, and similar rates among linezolid, tigecycline, or imipenem-based regimens.[43]

Amikacin ototoxicity rates have been reported at 23% in treatment of MAb; adverse effects, such as leukopenia (51%) or transaminase elevations (15%) are also commonly associated with cefoxitin.[43,44] Tigecycline often has significant gastrointestinal side effects.

Following induction, selected patients may transition to an oral regimen to extend at least 12 months past the time of culture conversion, if achieved. Another common approach is to complete several months of induction therapy as toxicity allows, followed by medication holidays. Surgical resection may contribute to sputum conversion in carefully selected patients with localized disease and adequate pulmonary reserve.

■ *Mycobacterium kansasii*

Mycobacterium kansasii is considered one of the most pathogenic NTMs, although almost all appropriately treated patients achieve sputum conversion.[45] Guidelines support the primary use of a three-drug regimen consisting of rifampin, ethambutol, and either isoniazid or a macrolide; a major consideration is the prevention of rifampin resistance.[18] Some data support three times per week dosing of a macrolide-containing regimen for *M. kansasii*, and either daily or three times per week dosing of a macrolide-containing regimen may be used for noncavitary disease.[46] For cavitary disease treated with any regimen or for noncavitary disease treated with an isoniazid-containing regimen, however, guidelines support daily dosing.[18] When rifampin resistance occurs, guidelines favor replacement with moxifloxacin. Sputum conversion is usually achieved by 4 months; the duration of therapy is 12 months. Rates of relapse are lower than in the treatment of MAC and MAb.[47]

■ *Mycobacterium xenopi*

Another pathogenic, slowly growing mycobacterial species with a greater incidence of cavitary disease is *M. xenopi*, which has been associated with 69% mortality; it is unclear to what extent the high mortality is due to *M. xenopi* itself.[11,48] Treatment may extend survival,[49] but a limited literature informs the current guidelines supporting use of three-drug therapy, including ethambutol and rifampin, plus either moxifloxacin or a macrolide. Interim analysis from a randomized trial of moxifloxacin versus clarithromycin as the third drug in this regimen has shown no difference in outcomes to date.[50,51] Based on potential severity of outcomes, guidelines also support a total duration of therapy of 12 months past the time of culture conversion as well as inclusion of parenteral amikacin in the regimens of patients with cavitary disease. Surgical intervention may also improve outcomes.[49]

MANAGEMENT OF COINFECTION

Coinfection with multiple NTMs is seen in up to 10% of patients. In such cases, combinations of MAC, *M. kansasii*, and/or *M. xenopi* are readily addressed by use of a guideline-supported regimen consisting of ethambutol, a rifamycin, and a macrolide.[18] Coinfection becomes more complicated, however, when considering the common combination of MAC and MAb, in which case an important branch point in treatment decision-making is macrolide susceptibility. If the MAb is macrolide-resistant, we treat MAC and MAb with non-overlapping regimens optimized for each pathogen, starting with MAC therapy, which is more likely to be tolerated; subsequently, agents active against MAb are added, once MAC therapy is established. When the MAb is macrolide-sensitive, use of a macrolide for both pathogens may simplify the overall regimen but complicate the initiation process. It may then be advisable to initiate treatment for MAC and MAb simultaneously to avoid development of MAb macrolide resistance while the patient is receiving *de facto* MAb macrolide monotherapy during initiation of the MAC regimen.

ADJUNCTIVE INTERVENTIONS

A major factor underlying pulmonary NTM infection is the presence of abnormal airway clearance contributing to the pathogenetic cycle of persistence, inflammation, and infection. Interventions geared at optimizing airway clearance and bronchiectasis management, such as nebulized hypertonic saline, flutter valve devices, or high-frequency chest wall oscillation vests are an important part of an overall treatment plan formulated among a multidisciplinary team, including pulmonology and chest physiotherapy. Although such interventions are not well studied or validated in cases of bronchiectasis outside the context of cystic fibrosis, in our clinical experience, patients with pulmonary NTM infections who engage in airway clearance regimens fare better than those who do not. These adjunctive interventions may also be helpful among patients for whom antibiotic therapy is not yet indicated, or for patients who are unable to tolerate antibiotic therapy. Given the high rates of esophageal dysmotility with fibronodular bronchiectasis and pulmonary NTM infections, prevention of aspiration events and management of esophageal co-pathology is also essential.

Limited data associate surgical intervention with improved outcomes in some pulmonary NTM infections.[36,44,49] Where indicated, these procedures, most often lobectomies, may be completed with relatively low morbidity and mortality; the most common complication is bronchopleural fistula associated with a high bacillary load or with right pneumonectomy.[52] Careful selection for patients with adequate pulmonary reserve and localized, refractory disease or complications, such as massive hemoptysis or resistant NTMs, is paramount.

NOVEL THERAPIES AND APPROACHES

A number of new pharmacologic agents for treatment of NTM respiratory infections are considered below.

Amikacin Liposome Inhalation Suspension

Amikacin liposome inhalation suspension (ALIS) carries the hypothetical benefits of local delivery to minimize systemic toxicity, enhanced macrophage uptake to improve intracellular drug delivery, and biofilm penetration.[53] The phase 3 CONVERT study demonstrated that addition of ALIS in patients who had received guideline-based therapy for MAC for at least 6 months led to a fourfold improvement in culture conversion rates.[53,54] These data followed a phase 2 study in which addition of ALIS in patients with persistently positive cultures resulted in a threefold increase in the number of patients with at least one negative sputum culture, although the primary endpoint of a decrease in semiquantitative NTM cultures narrowly missed significance; treatment may be less effective for MAb than for MAC.[55,56] Monitoring suggested nontoxic serum amikacin levels with inhaled therapy. No significant aminoglycoside-related toxicities were observed. Importantly, culture conversion was seen only among patients with amikacin MICs ≤64 μg/mL.[18,55]

Although ALIS is effective as an adjunct to standard of care, it has high rates of respiratory adverse events. More than 90% of patients in each arm of CONVERT experienced treatment-associated adverse events, most commonly within the first month of ALIS; particularly notable were dysphonia, cough, hemoptysis, and dyspnea, leading to discontinuation of ALIS in 17% of patients.[53] A later survey found similar symptoms among 73% of patients on ALIS. In most cases, symptoms are amenable to conservative interventions, such as lozenges, gargling, antitussives, evening administration of the drug, bronchodilators, or a brief treatment interruption with subsequent reintroduction.[57]

■ Clofazimine

Clofazimine has been in clinical use for the treatment of leprosy since the 1950s. The drug was used subsequently in the treatment of tuberculosis. In vitro studies generally show favorable MICs for clofazimine in the treatment of NTMs, although it may be less active against rapidly growing mycobacteria and *M. kansasii*. Synergy may be seen with some agents, such as amikacin, clarithromycin, or bedaquiline.[58,59] Animal models have generally supported antimycobacterial activity, although comparisons between rifampin- and clofazimine-based regimens have shown mixed results.[60,61]

Published clinical experience suggests 50% sputum conversion with clofazimine-containing regimens for treatment of MAb, MAC, or dual infection; 14% stop therapy due to adverse reactions such as gastrointestinal side effects or common dermatologic side effects of clofazimine, including skin discoloration (63%), dry skin (32%), or sun hypersensitivity (20%).[62] Conversion rates may improve among patients with more favorable clofazimine MICs (≤0.25 mg/L) and may be comparable to rifampin-containing regimens.[63,64]

In practice, we utilize clofazimine for MAC in patients unable to take first-line agents (more commonly rifamycins rather than ethambutol). When MICs are favorable, we also deploy clofazimine as part of salvage regimens for MAC or as part of an oral regimen for MAb. Outcomes in salvage therapy tend to be modest; series including clofazimine as part of salvage therapy have shown 16% to 29% favorable outcomes.[65,66] Access to clofazimine is complicated by its investigational status in the United States; for clinicians who are not part of a hospital or clinic that has a multipatient investigational agreement with Novartis, the only option is to submit a single-patient investigational new drug (IND) application to the U.S. Food and Drug Administration. Both require ethics approval in the treating clinicians' institutions.

■ Bedaquiline

Initially approved in 2012 for use against multidrug-resistant *M. tuberculosis*, bedaquiline exerts its antimycobacterial action by inhibiting the mycobacterial ATP synthase. NTM isolates from patients naïve to bedaquiline generally demonstrate favorable MICs.[58,67] Resistance to bedaquiline can be conferred by increased efflux pump expression, as well as direct alteration of the ATPase complex; the former is of particular concern, given its ability to confer cross-resistance between bedaquiline and clofazimine.[68,69] Synergy has been observed between bedaquiline and clofazimine, amikacin, and cefoxitin. Animal models have generally supported at least some degree of bedaquiline efficacy in the treatment of NTM infections in vivo.[70]

Although clinical experience is limited, an observational study of 10 patients taking bedaquiline as part of a regimen consisting of a mean of 5 drugs showed a microbiologic response in 6 patients at 6 months.[71] The most common side effects were nausea (60%), arthralgias (40%), and anorexia and subjective fever (30%); mild QTc prolongation was noted. Treatment may be complicated by selection for resistance while on therapy, necessitating implementation of an optimized regimen to preserve bedaquiline activity.[72] Use of bedaquiline is further complicated by interactions with rifampin, which substantially decreases bedaquiline levels compared with rifabutin. A final consideration is the long terminal half-life of bedaquiline (estimated at 5.5 months), which may lead to unintentional monotherapy when stopping regimens.[73] Rules for procurement of bedaquiline differ by country and may limit availability for use in the management of pulmonary NTM infections.

Novel Tetracyclines

Tigecycline is a glycylcycline tetracycline derivative that acts at the 30S ribosomal subunit. Unlike earlier tetracyclines, it is less susceptible to common resistance mechanisms, such as binding site alteration and efflux pumps in diverse bacteria as well inactivating enzymes associated with high level tetracycline resistance in MAb.[74,75] Its use in salvage regimens for MAb pulmonary infections is supported by in vitro susceptibility among rapidly growing mycobacteria (where MICs for slowly growing mycobacteria are generally unfavorable) and animal models. In observational studies, approximately two-thirds of patients on tigecycline-containing regimens showed improvement, typically when combined with macrolides, amikacin, linezolid, clofazimine, or imipenem; adverse effects, such as nausea (63.5%) and vomiting (34.6%), were common, necessitating a dose reduction or cessation of therapy in more than half of patients.[76,77] Starting treatment with 25 mg IV daily, followed by slow escalation over weeks to a target dose of 50 mg IV daily, may improve long-term tolerability.

Later-generation tetracyclines, such oral and intravenous omadacycline, have entered clinical practice more recently and are generally better tolerated than tigecycline; these carry the potential additional advantage of improved plasma and lung concentrations.[78] In phase 3 trials of omadacycline for non-NTM infections, the most common adverse effects were nausea (14.9%) and vomiting (8.3%); transaminase abnormalities were comparable with the comparators, linezolid and moxifloxacin.[79] Both omadacycline and eravacycline typically have favorable MICs against rapidly growing mycobacteria, such as MAb, where MICs against slowly growing mycobacteria appear generally unfavorable.[80] Published clinical experience to support efficacy remains limited to a handful of case reports.[81,82] Some rapidly growing mycobacteria and *M. kansasii* may also be susceptible to the older oral agent minocycline.

Oxazolidinones

Oxazolidinones target the 50S ribosomal subunit and are broadly active against Gram-positive bacteria. Both of the approved drugs in this class, linezolid and tedizolid, have some activity in vitro against most NTMs, although tedizolid is generally more potent.[83] Resistance to linezolid in MAC is conferred by mutations in the 23S rRNA gene *rrl,* as well as the *rplD* gene encoding the L4 ribosomal protein, in addition to efflux pumps.[84,85] A small series in the literature suggested improved sputum conversion rates from 29.4% to 81.3% when linezolid was added to standard therapy, although leukopenia and transaminase elevations were commonly encountered.[86] Linezolid carries a number of side effects that are less prominent than with tedizolid, including marrow suppression in 10% of patients treated for MAb.[43] When linezolid bone marrow toxicity occurs, use of tedizolid may still be possible.[87] Other adverse effects include optic neuritis, peripheral neuropathy for which vitamin B6 is typically coadministered, and the risk of serotonin syndrome when the drug is coadministered with other agents active in the inhibition of monoamine oxidases. We frequently use these agents in oral regimens for MAb, although adverse effects, particularly with linezolid, can be limiting.

Fluoroquinolones

Fluoroquinolones exert broad-spectrum antibacterial activity by inhibiting the normal function of DNA topoisomerases. They are variably active against MAC, MAb, and *M. kansasii*, although moxifloxacin tends to be the most active.[88,89] A number of resistance mechanisms have been demonstrated in typical bacteria, including direct changes in the topoisomerases themselves, although the details of fluoroquinolone resistance in NTMs remain unclear.[88] Published clinical experience is limited. One series looking at intensification of therapy with moxifloxacin for MAC resulted in sputum conversion in 12 of 41 patients who had refractory disease.[90] Another series comparing triple therapy, with or without levofloxacin for MAC, suggested lower sputum conversion rates in the presence of levofloxacin. The use of quinolones in combination with a macrolide has emerged as a risk factor for macrolide resistance.[36,91] Common adverse effects of fluoroquinolones include QTc prolongation and tendon rupture. Aside from *M. kansasii*, *M. xenopi*, and uncommon NTM species, quinolones are of limited utility in the management of NTM infections.

Phage Therapy

The rise of resistant organisms has rekindled interest in phage therapy as an alternative to antibiotics. The first human use of mycobacteriophage was reported in 2019 in a 15-year-old female with cystic fibrosis who had been treated for MAb for 8 years prior to bilateral lung transplant. The patient suffered disseminated infection following transplant that progressed through antibiotic therapy. Infection ultimately improved with a combination of three phages.[92] A more recent report from the University of California San Diego's Center for Innovative Phage Applications and Therapeutics showed that MAb and other NTMs are among the most frequent infections for which phages are requested. Although the cases described in this series did not include MAb, experience with typical bacteria indicated that intravenous administration of phages was safe, well tolerated, and translatable to the outpatient setting.[93] Although promising, phage therapy is investigational, and regulatory barriers and lack of experience limit the scalability of the approach at present.

SPECIAL POPULATIONS

Two special clinical circumstances warrant additional discussion: cystic fibrosis and lung transplantation.

Cystic Fibrosis

Patients with cystic fibrosis are disproportionately affected by NTM lung disease, and routine annual screening for NTMs is recommended.[94] Culture positive prevalence has increased by as much as 5% per year recently, reaching 20% in one study,[95] although most patients with a single positive culture do not progress to active disease.[96] Among those meeting criteria for infection, the most common pathogens are MAb among younger patients with severe disease and MAC among older patients with lower body mass index.[95] Although the source of NTM is usually environmental, gene sequencing supports a role for person-to-person transmission among patients with cystic fibrosis.[97] When NTM infection occurs, patients are at risk for a more rapid decline in lung function.[98] Infection may complicate potential future transplant[99] for the 16% (MAC) to 24% (MAb) of infected patients who progress to end-stage lung disease.[100]

The CFTR modulators ivacaftor and tezacaftor, as well as the antimycobacterial agent bedaquiline, are substrates for CYP3A4 enzymes that are strongly upregulated by rifamycins; coadministration of rifamycins with these medications is contraindicated. Clarithromycin, by contrast, is a CYP3A4 inhibitor that may increase exposure to CFTR modulators or bedaquiline. Other potential interactions of distinct or unknown mechanisms include decreased levels of linezolid and moxifloxacin in the presence of rifampin, and increased levels of linezolid in the presence of clarithromycin.[101] QTc-prolonging drugs include macrolides, clofazimine, bedaquiline, and fluoroquinolones. Gastrointestinal tract involvement may also lead to malabsorption, which may warrant therapeutic drug monitoring.

Management of pulmonary NTM infections in patients with cystic fibrosis typically follows guidelines for the general NTM patient population,[102] although some differences exist. Patients with cystic fibrosis were excluded from the CONVERT trial and fared worse in the prior phase 2 trial, although a small case series demonstrated clearance of cultures in three patients with cystic fibrosis who were placed on ALIS monotherapy.[56] Among a group of patients with cystic fibrosis in whom prior regimens had failed to yield sputum conversion, 50% achieved sputum conversion on a clofazimine-containing regimen,[62] while the sole published evidence for the use of phages for MAb derives from treatment of a patient with cystic fibrosis.[92,99] Prophylactic use of azithromycin in patients with bronchiectasis, both with and without underlying cystic fibrosis,[103–105] may reduce the rate of NTM infection. Its use in patients with underlying cystic fibrosis appears not to be associated with an increase in the isolation of macrolide-resistant strains.[106–108] Whether use of azithromycin may ultimately select for macrolide-resistant species and strains, such as MAb, has not yet been addressed in large studies.

■ Lung Transplantation

Although most pulmonary NTM disease occurs in the absence of immunosuppression, organ transplantation and other conditions that decrease cell-mediated immunity may predispose to both pulmonary and disseminated NTM infections.[9,109] Within the specific context of lung transplantation, MAb and MAC have most commonly been isolated from <1% to 7% of patients pre-transplant, and from 4.5% to 14% post-transplant, with the incidence of post-transplant isolation increasing over time to a peak of more than 20% at 5 years.[110–113] Several series have shown comparable survival, with and without pulmonary NTM infection, in the context of lung transplantation, although patients with NTM may be at increased risk of bronchiolitis obliterans syndrome; many centers consider NTM infection due to MAb at least a relative contraindication to transplantation.[99,110,111,114–116]

As in the case of cystic fibrosis, a major consideration in the management of pulmonary NTM infection in transplant patients is the potential for drug–drug interactions. Concerns center particularly on use of the rifamycins, which may significantly decrease levels of corticosteroids, tacrolimus, sirolimus, cyclosporine, and mycophenolate.[101] Clarithromycin, by contrast, may increase corticosteroid, tacrolimus, and sirolimus levels, while tigecycline may increase cyclosporine and tacrolimus levels.[101] Guidelines for the management of NTM infections in the context of transplantation support use of azithromycin and rifabutin as the preferred macrolide and rifamycin, respectively, due to their lower potential for drug-drug interactions.[117] Potential exists also for QTc prolongation with multiple agents, and coadministration of fluoroquinolones and corticosteroids may increase the risk of tendon rupture related to the former. Care should be taken in the context of nephrotoxic medications, such as amikacin, given the potential for additional nephrotoxic effects from some immunomodulatory medications.[101] To the extent possible, reduction of immunosuppression while still preserving optimal allograft function may also be part of treatment.[9,116,118]

FUTURE DIRECTIONS

Although much progress has been made in the diagnosis and management of pulmonary NTM infections, a number of knowledge gaps remain for further research, as has been highlighted by recent consensus statements on definitions of desired treatment outcomes and research priorities.[119,120] Among these, the clearest need is for more effective, better-tolerated, and overall simpler and shorter treatment regimens based on an enhanced understanding of NTM pathogenesis. Similarly, improved diagnostics for the identification and susceptibility testing of NTM isolates may help to facilitate more timely and efficacious treatment strategies.

CHAPTER 132

Aspergillus, Candida, and Other Opportunistic Pulmonary Mycoses

Georgios Chamilos
Dimitrios P. Kontoyiannis

INTRODUCTION

Pulmonary mycoses, mainly caused by *Aspergillus*, Mucorales, and other saprophytic molds are emerging diseases in the rapidly expanding population of immunocompromised patients. These opportunistic fungal pathogens cause a spectrum of pulmonary diseases depending on the severity of the underlying immunodeficiency. In particular, invasive mold infections are associated with considerable mortality despite appropriate antifungal therapy. Apart from improvements in establishment of timely diagnosis of pulmonary mycoses with establishment of non-culture-based diagnostic methods, there is a need to dissect the underlying mechanisms of immunopathogenesis in order to develop host directed therapies.

PULMONARY ASPERGILLOSIS

Aspergillus is a ubiquitous saprophytic mold that has a simple biologic cycle characterized by asexual reproduction and a high sporulating capacity, which results in the release of conidia at high concentrations (1–100 conidia/m^3) into the atmosphere. *Aspergillus* conidia have a diameter small enough (2–3 μm) to reach the pulmonary alveoli.[1,2] However, while humans may frequently inhale *Aspergillus* conidia, such conidia are effectively eliminated in immunocompetent individuals.[3]

Epidemiology

Infections by *Aspergillus* species cause a wide spectrum of illnesses in humans, which reflect the immune status of the host (Table 132-1). Hence, in immunocompetent hosts, isolation of *Aspergillus* spp. in respiratory secretions typically reflects colonization, not infection. In normal individuals, inhalation of *Aspergillus* spp. does not trigger immune responses because fungal spores are covered by a hydrophobic protein layer that masks recognition of immunostimulatory fungal cell wall polysaccharides by the immune system.[1–3] In atopic people, the fungus triggers robust immune reactions, including allergic rhinitis, asthma, hypersensitivity pneumonitis, and allergic bronchopulmonary aspergillosis (ABPA).[4] In patients with pre-existing cavitary pulmonary lesions (mainly as a result of prior tuberculosis), saprophytic growth of *Aspergillus* spp. can lead to aspergilloma formation or persistent inflammation, a disease entity called chronic pulmonary aspergillosis (CPA). Finally, in immunocompromised individuals, *Aspergillus* conidia may germinate in the lung to form hyphae, the invasive form of the fungus, which causes a severe, frequently fatal angioinvasive infection called invasive pulmonary aspergillosis (IPA).[5–7] The degree of fungal invasion, response to antifungal therapy, and outcome of invasive aspergillosis (IA) depend on the type and severity of immunosuppression. Thus, in patients with incompletely characterized, subtle immune defects, chronic forms of *Aspergillus* infections (CPA) in the lung have been described, which are characterized by an indolent clinical course, low-grade chronic inflammation, the development of progressive cavitary or fibrotic lesions, and minimal or no evidence of parenchymal invasion.[8] A less angioinvasive form of IA, frequently called subacute IPA, has been described in patients with genetic defects in NADPH oxidase (chronic granulomatous disease or CGD), whereas

TABLE 132-1 Spectrum of Pulmonary Aspergillosis

Clinical Manifestation	Immune Status	Underlying Lung Architecture	Degree of Tissue Invasion
Simple colonization	Normal	Chronic obstructive airway disease	None
Hypersensitivity reactions			
Allergic bronchial asthma	↑[a]	Normal	None
ABPA	↑	Excess airway mucus	None
Bronchocentric granulomatosis	↑	Excess airway mucus	None
Extrinsic allergic alveolitis	↑	Normal	None
Invasive infection			
IBA[b]	↑	Lung transplantation	++
Bronchial stump aspergillosis	Normal	Pneumonectomy	+
CPA[c]	↓[d]	Chronic obstructive airway disease	+
IPA[e]	↓↓↓[f]	Normal	+++

[a] ↑Hyperactive humoral response.

[b] Includes tracheobronchitis, pseudomembranous tracheobronchitis, and ulcerative tracheobronchitis. The latter two forms typically manifest as anastomotic infections in lung transplant recipients.

[c] Includes the following forms: aspergilloma, chronic necrotizing pulmonary aspergillosis (CNPA), chronic cavitary pulmonary aspergillosis (CCPA), chronic fibrosing pulmonary aspergillosis (CFPA). Aspergillus hyphae occasionally invade the lung parenchyma in CNPA. Significant overlap exists among these entities. Aspergilloma, previously regarded as saprophytic fungal growth, has been classified as a form of CPA.

[d] ↓Suppressed immune response.

[e] May have features of invasive disease surrounding the cavity. It occurs in two settings with distinct histopathologies and immunopathogenesis: angioinvasive IPA in profoundly neutropenic patients and nonangioinvasive IPA in immunocompromised nonneutropenic individuals, including those receiving corticosteroid-based treatment, recipients of HSCTs with severe GvHD, patients with AIDS, recipients of solid-organ transplants, and patients with CGD. Mixed forms and significant overlap exist.

[f] ↓↓↓Severely depressed immune response, neutropenia.

progressive IPA is encountered in severely immunocompromised hosts.[1,2,6,7] There is no doubt that since the first description in the 1940s, IA has emerged as the major problem of modern mycology. Currently, IA is a leading cause of death in severely immunocompromised individuals, with mortality rates up to 50% in patients with leukemia and recipients of hematopoietic stem cell transplants (HSCTs).[1,6] In addition, invasive *Aspergillus* has emerged as an important pathogen in an expanding spectrum of nonneutropenic patients with incompletely understood immunometabolic defects in myeloid phagocytes induced by prolonged receipt of corticosteroids, other immunosuppressive therapies, or underlying diseases. Thus, IPA is increasingly encountered in patients with inflammatory and autoimmune diseases, end-stage cirrhosis, chronic obstructive lung disease, and immunosuppression induced by viral or bacterial sepsis in patients with prolonged ICU stays.[1,2] At the same time, over the past two decades, we have witnessed a significant expansion in the antifungal armamentarium with the introduction of several agents with anti-*Aspergillus* activity. In addition, promising new non-culture-based diagnostic methods are being developed, and considerable progress has been made in understanding the epidemiology and immunopathogenesis of IA. As a result, a significant improvement in IA-attributable mortality has been noted. As IPA currently accounts for more than 90% of invasive *Aspergillus* infections we devote a significant portion of this chapter to this type of pulmonary aspergillosis.[1]

■ Mycology and Host Defenses

Of the nearly 200 *Aspergillus* spp., only 20 have been encountered as pathogenic in humans.[1] *Aspergillus fumigatus* is the most frequently identified of these species; however, other species, such as *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans* have emerged as important pathogens in immunocompromised individuals. Appropriate identification of *Aspergillus* species is important because of differences in epidemiology, host tropism, virulence, and susceptibility to antifungal agents. For example, *Aspergillus nidulans* is the second most encountered mold in CGD patients;[1,2] *A. nidulans* and other rare *Aspergillus* spp. cause almost exclusively invasive infections with distinct clinical features in patients with primary immunodeficiency. In addition, certain species including *A. terreus*, *A. flavus*, and *A. nidulans* are clinically resistant to AMB.[6,7] Studies using molecular identification methods discovered "cryptic" clinical isolates of *Aspergillus*, including *Aspergillus lentulus*, *Aspergillus calidoustus*, and *Aspergillus glaucus*, that had been misclassified as *A. fumigatus* and display inherent resistance to certain antifungal agents. Notably, *A. fumigatus* is nearly always the cause of allergic pulmonary disease.[4] *Aspergillus* spp. are rapidly growing, hardy molds identified by the macroscopic appearance of the colony and by microscopic examination of the spore-bearing structures.[1] Microscopically, *Aspergillus* spp. are characterized by the production of uniform 4- to 6-mm wide hyphae with parallel walls and distinct septa. Dichotomous branching of hyphae occurs at 45-degree angles.[1] However, other filamentous fungi, such as *Fusarium*, *Acremonium*, and *Scedosporium* species share the same histopathologic features with *Aspergillus* spp.[1] A wide range of microscopic appearances may be observed in clinical specimens.

Sputum specimens obtained from patients and examined by direct mounting or with KOH and ink may reveal the typical 45-degree branching hyphal fragments of aspergilli, which are often associated with eosinophils and Charcot–Leyden crystals in patients with ABPA.[1] Stained tissue sections reveal regular hyaline septate hyphae that are best observed with the use of periodic acid–Schiff (PAS) and Gomori methenamine silver (GMS) stain.[1] Fungus ball specimens obtained from cavities connected to bronchi have hyphae that often appear to be lifeless and stain poorly. Also, although seldom seen, the fruiting heads and conidia may appear to be well formed.

■ Host Immune Responses

Recent years have witnessed improvements in understanding of the immunologic mechanisms of host resistance to *Aspergillus* spp. Protection of the normal host against *Aspergillus* infection is mediated by a highly coordinated response that predominantly involves the innate immune system (Chapters 122 and 123).[1–3] IPA almost exclusively occurs in patients with defects in numbers and/or function of phagocytes. Acquired quantitative and qualitative defects in phagocytic function associated with prolonged and profound neutropenia and/or monocytopenia or corticosteroid-induced dysfunction of myeloid derived monocytes/macrophages have long been recognized as the major risk factors for IA. In addition, functional phagocytic defects due to mutations in NADPH oxidase seen in patients with CGD are associated with inflammatory immunopathology associated with inability to eliminate fungal conidia and unique susceptibility to IA.[3]

Overall, a balanced inflammatory response is required for abrogation or effective resolution of invasive *Aspergillus* infection. Thus, while an early and effective proinflammatory response is required to restrict infection, an uncontrolled inflammatory response is detrimental and may eventually facilitate fungal persistence. To that end, high-level production of IL-10 by T regs may be beneficial by contributing to resolution of the inflammatory response.[3] On the other side, IL-10 overproduction suppresses antifungal effector mechanisms and results in susceptibility for IA in human patients and mice.

Immune augmentation therapies have become a top priory in fungal immunology research.[2,3] However, in contrast to the animal studies, in severely immunocompromised patients with IPA, immune augmentation therapies have been of unclear benefit using myeloid growth factors, Th1 recombinant cytokines, or T cell–based adoptive transfer. Thus, translating recent advances in fungal immunology to novel therapeutics against IA in humans remains a challenge. In particular, translation of results of ex vivo experiments and studies in mice with genetic defects in receptors, signaling molecules, cytokines, or chemokines into clinical practice has been difficult in view of the complex and multifactorial pathophysiology of IPA in humans. Furthermore, immune augmentation strategies and vaccination-induced protective immune therapies could be suboptimal in profoundly immunocompromised individuals and should be tailored to the restoration of the underlying dominant immune defects of the individual patient. Better understanding of the immunopathogenesis of IPA at the cellular and molecular level coupled with efforts to validate research findings from mice in humans could facilitate the development of personalized immune-based augmentation therapies.

■ *Aspergillus* Virulence Factors

There is debate over which factors determine *Aspergillus* virulence and pathogenicity.[1,2] Several putative virulence factors in *A. fumigatus* have been identified, including various proteolytic enzymes (elastases, collagenases, trypsin), phospholipases, ribotoxin, hemolysin, gliotoxin, and many other enzymes and toxins.[1,2]

Importantly, tissue necrosis and angioinvasion are prominent features of IA in immunocompromised patients. Of interest, gliotoxin has been shown to block angiogenesis during invasive *Aspergillus* growth.[2,3] In fact, restoration of antiangiogenic activity of *Aspergillus* via administration of proangiogenic factors has been shown to potentiate activity of antifungal therapy in murine IPA. In addition, adaptation in the hypoxic environment during tissue necrosis is a prominent feature of invasive *Aspergillus* growth. In fact, an

Aspergillus mutant deficient in a sterol regulatory element-binding protein required for hypoxia adaptation (Δ*SrbA*) was completely avirulent in mice.[2,3] Iron metabolism is important for *Aspergillus* in vivo growth, and mutants defective in both intra- and extracellular siderophore production fail to grow in vivo and are avirulent following infection of neutropenic mice. Moreover, the melanin pigment and rigid protein coat layer composed of hydrophobic rodlet fascicles on the *Aspergillus* conidial surface confer resistance to phagocytosis and killing by the innate immune system.[2] In fact, melanin acts as a virulence factor by inhibiting calcium signaling regulating phagolysosomal fusion and killing of *Aspergillus* conidia by macrophages. On the other hand, comparative genomic analysis across filamentous fungi suggests that *A. fumigatus* virulence results from the immunosuppression or possibly genetic susceptibility of the host rather than from specific, unique fungal determinants.[2,3] Hence, *A. fumigatus* appears to be a saprotrophic fungus that only becomes pathogenic for very simple biologic reasons: it is present in high concentrations in the atmosphere, it grows faster than any other airborne fungi at physiologic mammalian temperatures (above 37°C), and it can overcome the defense of the host not because of specific virulence mechanisms but because of inefficient host innate immune responses. Taken together, these data suggest that approaches aiming at restoration of defective cellular immune responses via cytokine immunotherapy, treatment with checkpoint inhibitors, engineered effector cells, or dendritic cell vaccine–based vaccination warrant investigation as therapeutic modalities for invasive *Aspergillus* infections.[2,3]

Clinical Manifestations

The varied clinical manifestations of disease related to *Aspergillus* species are considered in detail below.

Hypersensitive Reactions

Hypersensitivity lung diseases that result from exposure to *A. fumigatus* allergens include allergic asthma, ABPA, and hypersensitivity pneumonitis.[4,6] In atopic individuals, inhalation of *Aspergillus* spores triggers an IgE-mediated allergic inflammatory response in the bronchial mucosa, leading to excessive mucus production, bronchial obstruction, and asthma.[4,6] Similarly, ABPA develops following sensitization to *A. fumigatus* allergens in a unique subset of atopic individuals and patients with cystic fibrosis (CF), who are genetically susceptible for ABPA.[4] The immune response to *Aspergillus* antigens in both patients with allergic asthma and those with ABPA is characterized by a robust Th2 polarized CD4+ response and eosinophilia, which are linked to polymorphisms in CARD9 signaling regulating IL-5 production in response to *Aspergillus*.

In nonatopic individuals, persistent airway colonization and, more rarely, a type of hypersensitivity pneumonitis called *extrinsic allergic alveolitis* can occur as a result of massive or repeated inhalation of *Aspergillus* conidia.[4,8] Hypersensitivity pneumonitis in these patients manifests with dyspnea because of pulmonary constriction and an influenza-like syndrome with fever, malaise, and fatigue. In contrast to other allergic diseases caused by *A. fumigatus*, hypersensitive pneumonitis is characterized by extensive infiltration of neutrophils in the acute phase as a result of a Th1 CD4+ response.[4,8] Early recognition of these syndromes is important for early initiation of appropriate treatment to prevent progression to permanent lung damage. Table 132-2 summarizes the hypersensitivity syndromes that result from exposure to *Aspergillus*.

Simple Colonization

Although there is not a uniform definition of colonization, it should be considered in cases of isolation of *Aspergillus* spp. from cultures of the respiratory tract in patients without evidence of invasive or allergic disease.[8] Patients with structural lung diseases such as chronic obstructive pulmonary disease (COPD) are at increased risk for persistent *Aspergillus* colonization. Furthermore, genetic susceptibility as a result of polymorphisms in the transcriptional factor ZNF77 impairs respiratory epithelial integrity and promotes *Aspergillus* colonization in patients with asthma and ABPA.[1] Tissue invasion by *Aspergillus* is not a feature of saprophytic colonization, although IPA following subsequent dysfunction of host defenses may develop. In fact, *Aspergillus* colonization has been shown to be a marker for the development of IA in immunocompromised individuals, particularly lung and bone marrow transplant recipients, and may precede invasion for up to 3 months.[7,8] Quantitative real-time polymerase chain reaction (PCR) and measurement of BAL *Aspergillus* galactomannan antigen are both highly sensitive and specific assays in distinguishing *Aspergillus* colonization from invasive infection.[1,6]

Allergic Bronchial Asthma

Asthmatic patients may become sensitized to *Aspergillus* conidia as a consequence of thick bronchial secretions that trap fungal spores.[4,8] These spores seldom germinate in the bronchial airways. Allergic bronchial asthma develops in patients who are atopic

TABLE 132-2 Hypersensitive Reactions to *Aspergillus*

	Asthma	ABPA	Extrinsic Allergic Alveolitis
Pathology	Hypertrophied mucus glands	Colonization of airways, viscid mucoid impaction, tissue eosinophilia	Lymphocytic infiltration of interstitium, noncaseating granuloma
Radiographic features			
Early	Normal, hyperinflation	Migratory peripheral infiltrates, atelectasis, bronchiectasis	Diffuse alveolar–interstitial infiltrates
Late	Normal, hyperinflation	Fibrosis	Reticulonodular interstitial opacities
Skin test reactions to *Aspergillus* antigens			
Immediate	Positive	Positive	Positive
Delayed	Negative	Positive	Positive
Peripheral eosinophilia	Negative[a]	Positive	Negative
IgG *Aspergillus* precipitins	Positive (up to 25%)	Positive	Positive
Serum IgE levels	Normal or mildly elevated	Marked elevation	Normal

[a] *Occasionally positive.*

and is perpetuated by inhalation of *Aspergillus* antigens, which typically triggers acute bronchospasm. The presence of transient infiltrates has been described during the immediate reaction but is not frequent. As is typical in asthma of other etiologies, eosinophils and serum IgE antibody are increased. Immediate skin reactions to *Aspergillus* antigens are positive, but specific precipitating antibodies (IgG) are usually negative.[4,8] Avoidance of exposure to *Aspergillus* allergens reduces asthma attacks in this group of patients. *Aspergillus* bronchitis is a rare, distinct clinical entity that has been recently described in immunocompetent individuals with structural lung disease, chronic pulmonary symptoms, and lack of response to antibiotic therapy. All of these patients had evidence of *Aspergillus* growth in their lungs, showed marked improvement following antifungal therapy, and did not fulfill criteria for asthma or other forms of invasive or chronic aspergillosis.

Allergic Bronchopulmonary Aspergillosis

The important clinical entity of allergic bronchopulmonary aspergillosis (ABPA) is discussed below. The reader is also referred to Chapters 46 and 51.

Immunopathogenesis and Risk Factors It has been recently proposed that ABPA develops in genetically susceptible patients with asthma or CF because of increased activity of *A. fumigatus*–specific Th2 CD4+ cells (Chapter 46).[4] Hence, in addition to a history of atopy, predisposing factors for ABPA include immunogenetic human leukocyte antigen (HLA)-distinct phenotypes (e.g., HLA-DR 2- and HLA-DR 5-specific alleles), mutations in the CF transmembrane conductance regulator (CFTR) gene, polymorphisms of the collagen region of the SP-A2, and/or other collectins (e.g., mannose-binding lectins), which collectively result in deregulated mucosal immune responses and chronic inflammation.[4,8] Additionally, genetic defects in epithelial integrity, associated with polymorphisms in transcriptional factor ZNF77, are associated with increased risk for ABPA.[1] Furthermore, epigenetic factors and environmental exposures may play a role in ABPA pathogenesis.[4,8]

In patients with ABPA, inhaled *A. fumigatus* conidia are able to colonize, persist, and germinate, leading to growth of hyphae in mucus plugs, which are often observed in expectorated sputum.[4] During this process, *A. fumigatus* releases a panel of proteases and other toxins that are capable of further compromising mucociliary clearance, breaching the airway epithelial barrier, and activating the immune system in the lung.[4]

IgE molecules on the surface of mast cells initially recognize *A. fumigatus* antigens. Binding of these antigens with IgE causes mast-cell degranulation, releasing mediators that cause vasodilatation and vascular leakage so that serum components, including anti-*Aspergillus* IgG, enter the bronchi and combine with *Aspergillus* antigens to form IgG-containing immune complexes.[4] These complexes activate the complement cascade leading to inflammation and pulmonary damage. Importantly, investigators have identified specific *Aspergillus* antigens capable of inducing IgE and IgG responses and aberrant immune responses selectively in patients with ABPA.[4]

Clinical Features ABPA is a hypersensitivity disease of the lung that is virtually almost always related to *A. fumigatus* (discussed in detail in Chapter 46). Some key points are highlighted here. Some 7% to 14% of patients with poorly controlled asthma and 7% to 9% of those with CF meet the diagnostic criteria for ABPA.[4] In fact, nearly all patients with ABPA have a history of chronic asthma. Rarely, patients present without symptoms or physical findings despite having radiographically detected abnormalities. Clinically, ABPA manifests with episodic wheezing, malaise, low-grade chronic fevers and cough, sputum containing brown flecks and plugs, chest pain, pulmonary infiltrates, and sputum and blood eosinophilia.[4,8] Patients may have a history of recurrent pneumonias and frequent use of antibiotic therapy. Mucus plugs form in the proximal bronchi and can progress to mucoid impaction, resulting in atelectasis with transient pulmonary infiltrates. Mucus plugs often yield aspergilli in culture (Figs. 132-1 and 132-2). As ABPA progresses, central bronchiectasis becomes a dominant feature of the disease and may result in chronic bronchorrhea and occasionally hemoptysis, development of clubbing, and fixed, characteristic radiographic abnormalities.[4,8] In patients with CF in particular, ABPA often manifests with hemoptysis and may be complicated by pneumothorax.[4]

Radiographic Findings The radiographic features of ABPA have an essential role in diagnosis, as they may distinguish ABPA from simple, chronic asthma. Pulmonary infiltrates in cases of ABPA are initially transient, but they ultimately progress to permanent radiographic changes.[4,8] In many instances, the "ring sign" indicative of bronchial wall thickening, "parallel" shadows or "tram lines" suggestive of bronchiectasis, and branching "finger-in-glove" opacification of the dilated bronchi because of mucoid impaction are seen on regular chest radiographs of patients with ABPA (Fig. 132-3).[4,8] The presence of proximal bronchiectasis (Figs. 132-3 and 132-4), which is characterized by normal filling of bronchi distal to the saccular bronchial lesion, is considered a hallmark for the diagnosis of ABPA.[4] ABPA lesions are either focal or bilateral and tend to occur more frequently in the upper lobes. Late radiographic findings in patients with ABPA include cavitation, local emphysema, contracted upper lobes, and honeycomb fibrosis.

Chest computed tomography (CT) has been a significant aid in diagnosing ABPA because it is more sensitive than regular chest radiography; however, there are no pathognomonic CT findings for this entity.[4,8] Besides central bronchiectasis, CT findings highly suggestive of ABPA include the presence of varicose or cystic bronchiectasis of segmental and subsegmental bronchi (90% in ABPA vs. 30% in simple asthma), mucoid impaction of the segmental and subsegmental airway (67% in ABPA vs. 4% in simple asthma), and small airway abnormalities such as centrilobular nodules and tree-in-bud opacities (93% in ABPA vs. 28% in simple asthma).[4,8] In patients with CF especially, CT diagnosis of ABPA is particularly challenging, as there is a significant overlap in the radiographic features of both entities.[4] In fact, the presence of high-attenuation mucus plugs because of dystrophic calcification is the only CT finding that favors the diagnosis of ABPA in patients with CF.

Diagnosis The "classic" patient with ABPA fulfills the criteria listed in Table 132-3. It has been suggested that the minimal essential criteria for the diagnosis of ABPA include the presence of (a) asthma, (b) immediate cutaneous reactivity to *Aspergillus* antigens, (c) elevated total serum IgE levels (>1000 U/mL), (d) elevated serum IgE and

TABLE 132-3 Criteria for the Diagnosis of Allergic Bronchopulmonary Aspergillosis (ABPA)

Primary
- Episodic bronchial obstruction (asthma)
- Peripheral blood eosinophilia (>1000/mm^3)
- Immediate-type skin reactivity to *Aspergillus* antigens[a]
- Precipitating serum antibodies (precipitins) against *Aspergillus* antigens[a]
- Elevated serum IgE concentrations (>1000 ng/mL)[a]
- Elevated serum IgE and/or IgG antibodies specific to *A. fumigatus*[a]
- History of pulmonary infiltrates (transient or fixed) on chest radiographs or CT scans
- Central bronchiectasis on chest CT scans

Secondary
- *A. fumigatus* in sputum (by repeated culture or microscopic examination)
- History of expectoration of brown plugs or flecks
- Arthus reactivity (late skin reactivity) to *Aspergillus* antigen

[a] *Test must be positive for serologic diagnosis in asymptomatic patients.*

IgG levels to *A. fumigatus,* and (e) central bronchiectasis.[4,8] However, asymptomatic pulmonary involvement occurs in patients with ABPA and may lead to diagnostic uncertainty, delayed diagnosis, and irrevocable structural lung damage. Furthermore, corticosteroid-based therapy for asthma may mask the signs of ABPA, leading to a progressive decline in pulmonary function. Because the above criteria may not apply in such cases, ISHAM proposed updated criteria for diagnosis of ABPA, which have been recently validated and shown to be more sensitive for diagnosis of ABPA.[4,8] The updated criteria define asthma or cystic fibrosis as predisposing conditions and require two obligatory criteria: (1) immediate cutaneous hypersensitivity to *Aspergillus* antigen or elevated IgE levels against *A. fumigatus*, and (2) elevated total IgE levels, and the presence of at least two out of three minor criteria, for ABPA diagnosis: (1) presence of precipitating or IgG antibodies to *A. fumigatus*, (2) radiographic features in the lungs consistent with ABPA, and (3) peripheral blood eosinophilia. In addition, the diagnostic criteria for ABPA in patients with CF were recently modified because of the overlapping features between these entities. The new criteria consist of (a) clinical and/or pulmonary function deterioration from baseline status, (b) positive immediate cutaneous reaction to *A. fumigatus* antigens or elevated IgE *A. fumigatus* antibody serum level, (c) elevated serum total IgE level >1000 U/mL, (d) elevated serum IgG *A. fumigatus* antibody level or positive *A. fumigatus* precipitins, and (e) abnormal chest imaging findings or a change in baseline abnormalities.[4]

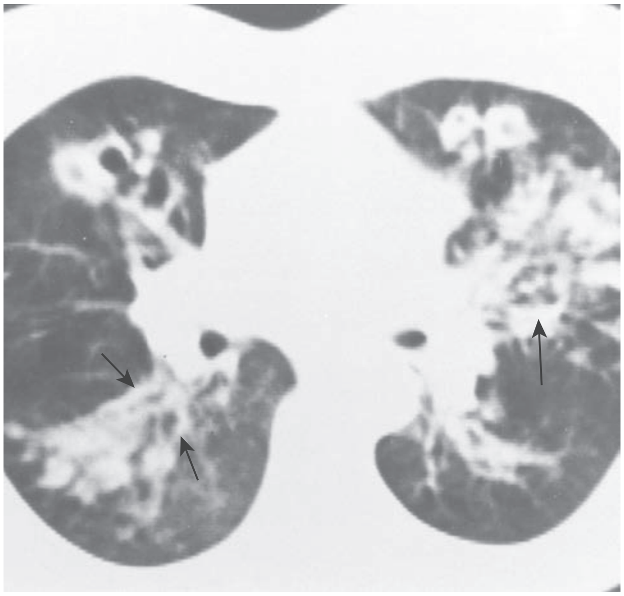

Figure 132-4 Proximal saccular bronchiectasis characteristic of ABPA. The CT scan reveals multiple rounded, dilated bronchi *(small arrows)*. Of note is the air–fluid level *(large arrow)*. *(Reproduced with permission from Drs. S. Albelda and G.H. Talbot.)*

Important clinical clues that should alert clinicians to the possibility of ABPA include refractory asthma or asthma with any of the following features: bronchiectasis, radiographic infiltrates, prominent eosinophilia, and expectorated brown plugs that may contain eosinophils or hyphae (Fig. 132-2).[4] In addition, in patients with CF, prominent wheezing is considered to be suggestive of ABPA. Rarely, ABPA may be caused by non-*fumigatus* aspergilli or other fungi; in such cases, the serological tests will be negative.

Because no single clinical or immunologic feature is diagnostic for ABPA, this disease is underdiagnosed. In the past, serologic diagnosis of ABPA was based on *Aspergillus* crude extracts, a laborious process with low specificity and reproducibility. However, the use of standardized recombinant *A. fumigatus* allergens substantially improved the specificity and sensitivity of diagnosis of *A. fumigatus*–related diseases, including ABPA.[4,8] Several recombinant *A. fumigatus* allergens, including Aspf1, Aspf2, Aspf3, Aspf4, Aspf6, and Aspf16, show high specificity for the detection of sensitization to *A. fumigatus* and for the diagnosis of ABPA and appear to be superior to crude *Aspergillus* allergen extracts.[4] However, because the sensitivity of each recombinant *A. fumigatus* allergen is suboptimal, use of a panel of recombinant allergens is favored to increase the sensitivity of the diagnosis of ABPA. Further standardization and development of commercially available immunoassays containing a combination of these allergens holds promise for improving the diagnosis of ABPA.

Because patients with CF are at high risk for ABPA, initiation of annual screening in patients with >6 years of age for ABPA with monitoring of serum total IgE levels has been recommended with further diagnostic workup for ABPA in cases with IgE levels >500 U/mL.[4] Likewise, because treatment with corticosteroids has a significant impact on disease progression, screening CT has been advocated for asthmatics with a skin-prick hypersensitivity test positive for *A. fumigatus* extracts to identify ABPA at an early stage.[4,8]

Histopathology Because the diagnosis of ABPA is based on clinical and laboratory criteria, use of lung biopsy to confirm the diagnosis is usually not required. The presentations of the hypersensitivity syndrome associated with fungi are discussed in detail in Chapter 46. Some of the histopathologic presentations associated with ABPA overlap those of invasive *Aspergillus* infection. Thus, eosinophilic infiltrates may be present in patients with a chronic invasive *Aspergillus* infection as well as in those with other allergic lung entities, such as Löffler syndrome, tropical eosinophilic pneumonia, and chronic eosinophilic pneumonia (Chapter 71).[4,8] Mucoid impaction associated with ABPA or other fungi may predispose patients to bacterial superinfection (Figs. 133-1 and 133-2). Necrotizing granulomas in association with the presence of *Aspergillus* spp. in asthmatic patients may be observed and is considered part of the ABPA syndrome.[4,8] The histopathologic distinction between ABPA, with fungal elements restricted to the airways, and semi-invasive or fully IA may be obscured by tissue necrosis or poor granuloma formation. These presentations are discussed further below.

Treatment ABPA may progress through five stages based on clinical, serologic, and radiographic findings, which are summarized in Table 132-4.[4,8] Importantly, the first four stages are potentially reversible without long-term sequelae; only the last stage, which is characterized by fibrosis and bronchiectasis, is irreversible. The goals of therapy for ABPA are to treat acute exacerbations of disease and prevent the development of fibrosis and bronchiectasis. Therefore, early diagnosis of ABPA before permanent lung damage occurs is critical. Therapeutic modalities for ABPA include oral corticosteroids, metered-dose inhaler medications, and systemic antifungal agents.[4,8] Omalizumab, a humanized monoclonal antibody against IgE that is an approved therapy for severe asthma, has been used for refractory cases of ABPA.[4,8]

Use of oral corticosteroids remains the cornerstone of the treatment of ABPA.[4,8] These agents suppress the inflammatory response provoked by *Aspergillus* infection rather than eradicate the fungus. Recent studies validate the use of a low-dose steroid regiment in management of ABPA. Recommended corticosteroid doses for acute exacerbations of ABPA are 0.5 to 1.0 mg/kg of prednisone equivalent daily for 1 to 2 weeks, followed by 0.5 mg/kg per every other day for 6 to 12 weeks. The physician should then attempt to taper the patient's corticosteroid dosage. However, some patients cannot be successfully weaned off corticosteroids and may require a daily maintenance dose of at least 7.5 mg.

Increasingly, use of itraconazole, an azole antifungal with activity against *Aspergillus* spp., has been employed as adjunctive fungal antigen–reducing therapy for ABPA, especially in patients with frequent relapses or corticosteroid dependence.[4,8] A randomized controlled study reported that oral administration of itraconazole (200 mg twice daily) was beneficial in terms of significant improvement of symptoms, pulmonary function, chest radiographic findings, and serum IgE levels in asthmatic patients with ABPA; uncontrolled studies suggested a similar benefit in patients with CF and ABPA.[4,8] However, use of itraconazole requires determination of drug levels to ensure adequate absorption and poses significant issues with long-term tolerability and drug–drug interactions.[5,6] Another important issue of prolonged itraconazole use is the emergence of azole-resistant *Aspergillus* isolates. In addition, itraconazole has a 40% failure rate in ABPA treatment.[6] The newer triazole voriconazole has improved fungicidal activity against *Aspergillus* spp. and better bioavailability when compared with itraconazole.[5,6] A recent retrospective study in 20 ABPA patients who failed or were intolerant to itraconazole and received either voriconazole or posaconazole found sustained clinical and immunologic responses and reduced corticosteroid requirements at 12 months in over 75% of treated patients.[5–7] However, high relapse rates (up to 57%) have been reported following discontinuation of azole treatment in patients with ABPA, and there are concerns for the development of secondary resistance in *Aspergillus* following prolonged courses of antifungal therapy.

Use of inhaled corticosteroids may help control the symptoms of asthma but does not prevent episodes of eosinophilic infiltration and mucus impaction and is generally thought to have no influence on progressive lung damage.[4,8] Inhaled bronchodilators such as β-agonists, anticholinergics, and leukotriene antagonists may be

TABLE 132-4 **Staging System for Allergic Bronchopulmonary Aspergillosis (ABPA)**

Stage	Symptoms	Radiographic Features	Laboratory Features	Management
I. Acute	Fever, productive cough, wheezing	Pulmonary infiltrates, mucoid impaction	Blood eosinophilia, elevated serum IgE level, positive skin test	Corticosteroids to achieve remission
II. Remission	Asymptomatic	Normal	Decrease in IgE and blood eosinophilia	Careful follow-up
III. Exacerbation	All or some of acute-stage symptoms	All or some of acute-stage findings	At least a doubling of IgE in asymptomatic patients and an increase in IgE in symptomatic patients	Retreat with steroids to induce remission
IV. Corticosteroid dependent	Symptomatic steroid-requiring asthma	Variable	Usually continued elevation of IgE	Long-term steroids to control asthmatic symptoms and keep IgE levels at baseline
V. Fibrotic	Severe dyspnea, fibrotic lung disease, as well as bronchospasm	Pulmonary fibrosis	Restrictive plus reversible and irreversible obstructive function tests; may have continued increased IgE	Long-term corticosteroid use

Data from Mendelson EB, Fisher MR, Mintzer RA, et al. Roentgenographic and clinical staging of allergic bronchopulmonary aspergillosis. Chest. 1985;87(3):334–339 and Patterson R, Greenberger PA, Radin RC, et al. Allergic bronchopulmonary aspergillosis: staging as an aid to management. Ann Intern Med. 1982;96(3):286–291.

used to treat asthma-related symptoms.[4,8] Inhaled antifungal agents such as nystatin and amphotericin B deoxycholate (AMB-D) may offer temporary suppression of colonization, but penetration of these agents into plugged bronchi is limited and recolonization rapidly occurs once therapy ends. When combined with oral steroid treatment, nebulized AMB has been an effective option to reduce ABPA exacerbations. Meticulous bronchial toilet is important for clearance of *A. fumigatus* from the airway. Thus, physical therapy with postural drainage is an important adjunctive treatment. Increased hydration, use of expectorants, and, in selected patients, bronchial lavage may aid in viscid mucus clearance. Avoidance of environmental reservoirs of *Aspergillus* spp. such as compost heaps, grain silos, and decayed organic matter may help prevent exacerbation of ABPA. In patients with CF ABPA, differentiating between a bacterial exacerbation of CF and an ABPA flare is important, because initiation of corticosteroids may have detrimental effects in patients with bacterial infection; a serologic assessment is essential as part of this evaluation.[4]

Immunotherapy with the injection of conventional allergens has not been shown to be of value for ABPA.[4,8] However, newer immunomodulatory approaches, including immune modulation toward a Th1 response by using *A. fumigatus* synthetic peptides, DNA-based vaccines, and immunostimulatory molecules such as cytosine polyguanine oligonucleotides, are being explored in animal models with promising results. Recently, a placebo-controlled study of omalizumab in a small group of patients with ABPA was associated with a significant reduction in disease exacerbations and improvement in immunologic parameters.[4]

Monitoring of treatment efficacy and toxicity is imperative. Long-term follow-up of patients with ABPA has shown that increasing serum levels of IgE is often a harbinger of a clinical flare of the disease and that the levels of IgE decline correlate with a clinical response to corticosteroids.[4,8] Thus, a prudent course of action is to determine baseline serum IgE levels when ABPA has been controlled by corticosteroid-based therapy and then monitor serum IgE levels regularly (every 1–2 months). Total serum IgE levels usually should decrease by at least one-third within 6 weeks from the initiation of corticosteroid-based treatment; infiltrates should be resolved after 1 to 2 months, and the results of pulmonary function tests should improve. Although serum IgE levels seldom return to normal, reinstitution of corticosteroids should be considered even in asymptomatic patients if the serum IgE level is double that of the baseline value.[4,8] In patients with symptomatic ABPA, chest radiographs should be obtained every 3 months during the first year of follow-up and yearly thereafter; pulmonary function tests should also be performed yearly.[4,8] However, no one has identified certain prognostic indicators for progression or regression of ABPA, and whether “pre-emptive” treatment of asymptomatic flares alters the natural history of the disease remains controversial.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis is a rare hypersensitivity syndrome that is characterized histologically by replacement of bronchial mucosa with necrotizing granulomatous tissue.[8] Also, eosinophilic infiltration of bronchioles and fibrosis is prominent, whereas there is no evidence of *Aspergillus* invasion. *Aspergillus* hyphae have been demonstrated within the lesions in approximately half of the cases of bronchocentric granulomatosis. This syndrome is associated with asthma in half of the patients described and likely represents a severe exuberant focal manifestation of ABPA rather than the more generalized pulmonary pathology evident in patients with ABPA.[8] Patients typically present with chronic symptoms, such as malaise, cough, low-grade fever, dyspnea, dull chest pain, and hemoptysis associated with a focal lesion on chest radiographs, often in an upper lobe. Occasionally, radiographic findings of multiple nodular or mass-like lesions simulate metastatic carcinoma.[8] Diagnosis of bronchocentric granulomatosis is made based on biopsy or often retrospectively after removal of the lesion, which is curative. Some patients, especially those with multifocal lesions, may need corticosteroid-based therapy for ABPA.[8]

Extrinsic Allergic Alveolitis

Heavy or repeated exposure to *Aspergillus* conidia and mycelia may result in a hypersensitivity reaction affecting the alveoli in nonatopic individuals known as *extrinsic allergic alveolitis* (Chapter 58).[8] Malt workers, distillers, brewers, and others exposed to moldy straw or grain have suffered attacks consisting of cough, dyspnea, fever, chills, myalgia, and malaise 4 to 8 h after exposure to *Aspergillus* antigens.[8] Repeated exposures may lead to malt worker’s lung or farmer’s lung or to the development of granulomatous disease or interstitial fibrosis. The immunopathogenesis of extrinsic allergic alveolitis involves cell-mediated immunity (type IV response) and immune complex deposition (type III response) and likely involves an intricate interaction between these immune mechanisms.[8]

Radiographic changes in the acute syndrome include diffuse alveolar–interstitial infiltrates that may resolve with the removal of the inciting antigen. Patients with chronic extrinsic allergic alveolitis may have fine reticulonodular interstitial infiltrates that may progress to pulmonary fibrosis with honeycombing.[8] Serum IgG antibodies (precipitins) against *Aspergillus* antigens are present in patients with extrinsic allergic alveolitis; however, the serum IgE level is typically normal. Skin tests usually demonstrate an Arthus reaction at 4 to 8 h and occasionally may be preceded by an immediate wheal and flare reaction and followed by a delayed reaction (36–48 h afterward). Removal or avoidance of the source of antigen exposure is crucial in the management of extrinsic allergic alveolitis, as spontaneous recovery often ensues once exposure has ended.[8] Administration of corticosteroids is helpful in aiding the resolution of acute symptoms and reduces the likelihood of structural damage. However, corticosteroids are not helpful once fibrosis has developed.

Aspergilloma

Saprophytic colonization of a parenchymal lung cavity by *Aspergillus* is referred to as *aspergilloma*, *mycetoma*, or a *fungus ball.*[8] Spontaneous shrinkage or disappearance of aspergilloma has been reported in 7% to 10% of cases and is often associated with bacterial superinfection of the cavity.[8] Aspergillomas only rarely increase in size. Most aspergillomas are caused by *A. fumigates*, but some, especially in patients with diabetes mellitus, are caused by *A. niger*, in which case oxalic acid crystals may be seen in the sputum.[8] Rare cases of extrapulmonary sites of aspergillomas involving the skin, brain, retroperitoneal area, and sinuses have been described. Recently, aspergilloma has been classified as a form of chronic pulmonary aspergillosis (CPA).

Pathophysiology The pathogenesis of aspergilloma usually involves colonization and proliferation of the fungus in a pre-existing pulmonary cavity (secondary aspergilloma). The cause of a pre-existing cavity is most commonly prior cavitary tuberculosis; aspergilloma has been reported in 11% to 17% of patients with posttuberculosis cavities.[8] In fact, 20% of patients who recover from cavitary tuberculosis develop aspergillomas within the next 3 years. Of interest, in developing countries tuberculosis is the predisposing factor for over 90% of cases of aspergilloma. However, an aspergilloma may complicate a wide spectrum of cavitating pulmonary diseases, such as sarcoidosis, histoplasmosis, blastomycosis, AIDS (especially in cases of atypical *Pneumocystis jiroveci* pneumonia), pneumonia and/or lung abscess, pulmonary or bronchial cysts, bronchiectasis, pulmonary fibrosis, asbestosis, adenocarcinoma, ankylosing spondylitis, rheumatoid nodules, cyanotic heart disease, and pulmonary infarction.[8]

Primary aspergilloma, which arises within the bronchial tree with the proliferation of *Aspergillus* leading to a pulmonary cavity, is far less common. The clinical conditions leading to the initiation of a cavitary process and formation of a fungus ball include IPA, chronic necrotizing pulmonary aspergillosis (CNPA), and ABPA. IPA may lead to primary aspergilloma during bone marrow recovery, as the host is able to mount an inflammatory response and ward off the fungus. Pneumothorax may be a severe complication of pulmonary mycetoma that is reported as a rare occurrence in patients with hematologic malignancies.[8] ABPA may cause bronchiectasis in the chronic phase of the disease and result in aspergilloma secondary to growth of a fungus distal to a plugged bronchus.[4,8] In fact, aspergillomas have been found in 7% of patients with ABPA in one study. Thus, aspergilloma may provide a stimulus for the perpetuation of ABPA.

Typical biofilm structures have been observed in aspergillomas from patients and in a murine model of IPA. Defective extracellular matrix penetration by most antifungal agents makes them significantly less effective when *A. fumigatus* is grown under biofilm versus planktonic conditions. Thus, chronic exposure and suboptimal azole concentrations in fungal biofilms could explain the emergence of azole-resistant *A. fumigatus* isolates reported in these patients.[2,3,8]

Clinical Features/Diagnosis Hemoptysis is the typical manifestation of aspergilloma, as it is seen in 50% to 90% of patients.[8] Hemoptysis is typically infrequent and mild but can be occasionally massive or even fatal. The diagnosis is usually made based on clinical and chest radiographic features coupled with serologic evidence of precipitating antibodies to *Aspergillus* spp.

Chest radiographs reveal a solid round mass within a cavity (3–5 cm diameter) partially surrounded by a radiolucent crescent (Monod's sign) (Fig. 132-5).[8] Movement of the fungus ball within

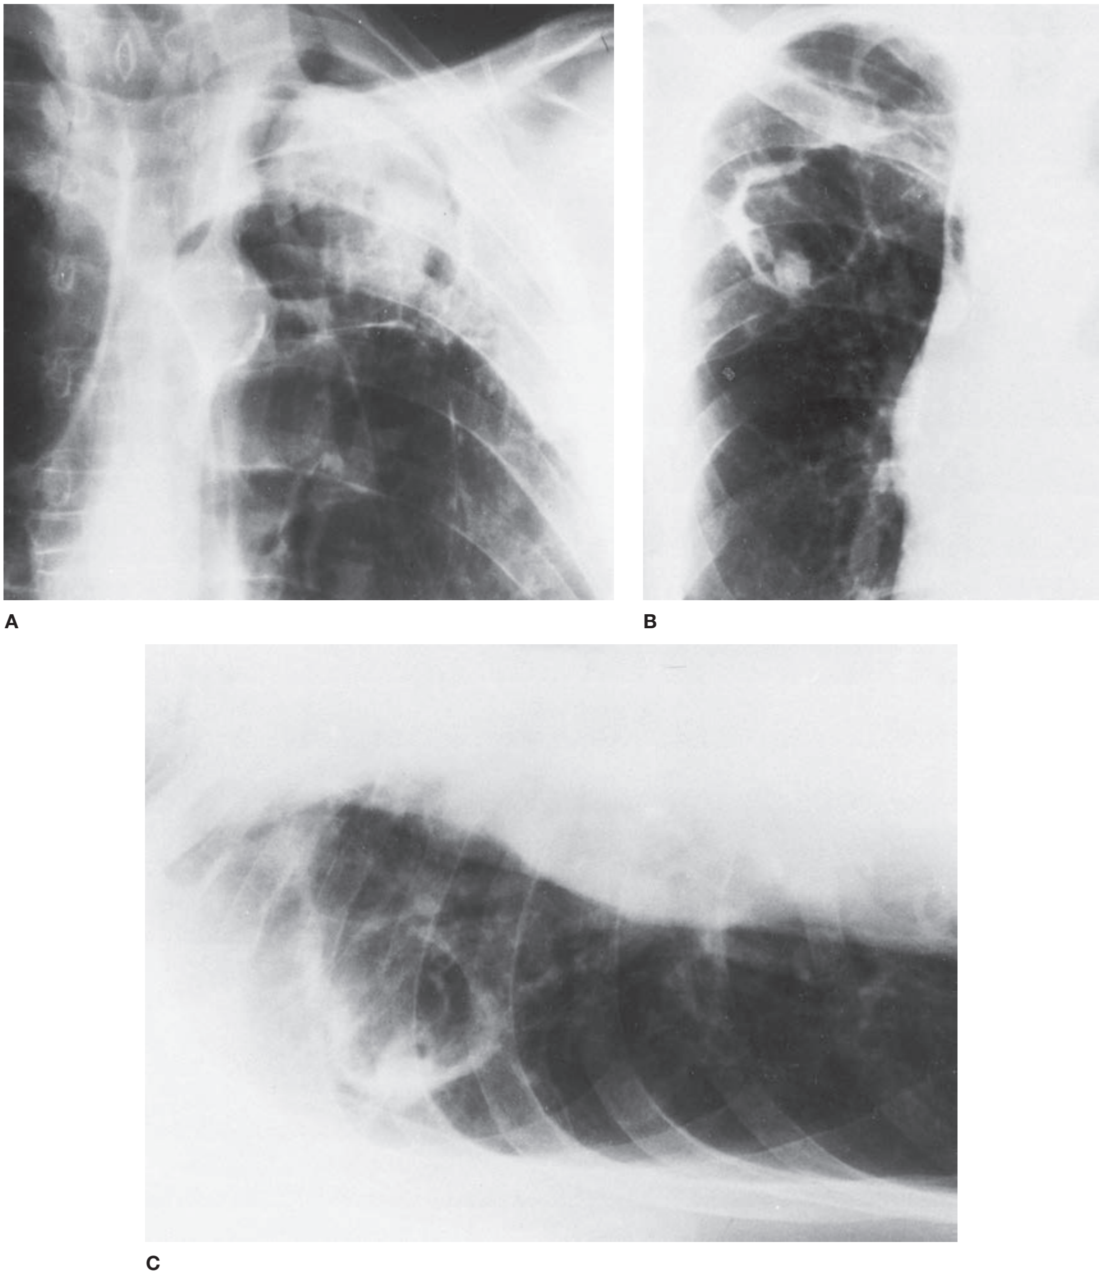

Figure 132-5 Radiographic appearances of pulmonary aspergillomas. **A.** A 51-year-old man with a history of tuberculosis showing the classic crescent-shaped patch of air (Monod's sign) as well as marked pleural thickening. **B.** A 49-year-old man with ankylosing spondylitis in whom an aspergilloma developed inside a thin-walled cavity. **C.** Decubitus film of the patient in **B** showing a fungus ball that moved when the patient changed position. *(Reproduced with permission from Drs. S. Albelda and G.H. Talbot.)*

the cavity may be appreciated when comparing upright and decubitus images. A solitary lesion in the upper lung fields is the most common radiographic feature of aspergilloma, as pre-existing tuberculosis cavities is the most common predisposing condition. However, aspergillomas can be bilateral and multiple. In many cases, chest CT may be helpful in further delineating the radiographic features of an aspergilloma that are not apparent on chest radiographs. On CT scans, globules of gas are often seen within the hyphal mass. CT angiography may also provide useful information for patients with hemoptysis by identifying hypertrophic bronchial arteries that often supply the cystic wall of aspergillomas.[4,8]

Although sputum cultures are positive for *Aspergillus* in more than half of all patients with aspergilloma, culture is not a sensitive and specific diagnostic marker.[8] Precipitating antibodies to *Aspergillus* antigens are present in the sera of more than 95% of patients with aspergilloma; however, some patients receiving corticosteroids may be seronegative.[8] Eosinophilia, IgE, and skin-test reactivity may be seen in individuals who are allergic to the fungus, but these are not consistent findings. Therefore, a positive precipitin reaction for *Aspergillus* is particularly helpful in establishing the diagnosis of aspergilloma. Clinical judgment and a low threshold for performing serologic diagnostic workup, BAL, or a lung biopsy in atypical cases are required.

Predictors of poor prognosis for aspergilloma include a progressive increase in the size and/or number of aspergillomas, severe underlying lung disease with a poor lung reserve, immunosuppressive therapy, AIDS, sarcoidosis, a rising *Aspergillus*-specific IgG titer, and repetitive episodes of severe hemoptysis.[4,8]

Treatment There is no consensus on the treatment of aspergilloma because of a lack of controlled studies. Because life-threatening hemoptysis occurs only in a minority of patients, subjecting all patients with aspergilloma to surgical therapy, which is often associated with significant morbidity and mortality, seems to be inappropriate.[8] Management options for aspergilloma currently include systemic or local administration of antifungal agents, surgical resection, and conservative management with careful follow-up without specific medical or surgical intervention.[8] Often, the best course of action for asymptomatic patients with aspergilloma is carefully repeated clinical evaluation with periodic chest radiographs without surgical intervention. Therapeutic considerations must include the individual patient's health status with attention to the potential risks of each treatment.

For patients who are unfit for surgical resection, an alternative approach is cavernostomy, which is performed under local anesthesia; however, cavernostomy is also associated with mortality and mediocre results.[6,8] This procedure should be considered as a last resort.

Intracavitary instillation of an antifungal agent is a promising alternative treatment in patients with severe pulmonary dysfunction who are poor candidates for surgery. CT-guided percutaneous instillation of AMB-D has been shown to be effective for aspergilloma in several cases of massive hemoptysis, with resolution of hemoptysis within 5 days.[8] Endobronchial instillation of ketoconazole via fiberoptic bronchoscopy also has been successful.[8]

Bronchial arterial embolization (BAE) has been extensively used in the management of hemoptysis in patients with aspergilloma.[4,8] Hence, BAE seems to be appropriate only as a "bridge" procedure in patients with massive hemoptysis until surgical resection of the aspergilloma can be performed. Also, radiation therapy has been shown to be effective for aspergilloma, even in patients with massive hemoptysis.[4,8] This modality has been recommended for cases of recurrence of life-threatening hemoptysis after BAE.

Itraconazole is an orally administered antifungal agent with activity against *A. fumigatus* and high tissue penetration into the lung. The use of itraconazole for aspergilloma has been reported in several noncontrolled studies.[4,8] Data from these studies showed that the use of itraconazole capsules at doses ranging from 200 to 400 mg/d for 6 to 18 months resulted in radiographic and symptomatic improvement in almost two-thirds of the patients and may have a place for the treatment of aspergilloma.[8] Recurrence of aspergilloma often follows discontinuation of itraconazole treatment, whereas acquisition of secondary resistance of *A. fumigatus* isolates to itraconazole has been described in patients with aspergilloma following prolonged treatment. Voriconazole has been successfully used to treat pulmonary aspergilloma caused by itraconazole-resistant *A. fumigatus* isolates, although cases of voriconazole failure in patients with aspergillomas have also been reported. There is evidence of development of secondary resistance to voriconazole during long-term treatment of patients with aspergillomas.

Invasive Bronchial Aspergillosis

The term *invasive bronchial aspergillosis* (IBA) refers to infection involving the large airways. Further subclassification of IBA based on the bronchoscopic appearance has been proposed, including tracheobronchitis, pseudomembranous tracheobronchitis, and ulcerative tracheobronchitis. In fact, these entities represent a continuous spectrum of this infection.[7,8] An alternative, more functional classification based on the depth of tissue invasion by *Aspergillus* includes (a) superficial infiltration type; (b) full-layer involvement type; (c) occlusion type (airway occlusion ≥50% of the original diameter of involved bronchi); and (d) mixed type. The potential impact of this classification system on the management of IBA has not been validated.

Aspergillus tracheobronchitis is the least invasive form of IBA and is characterized by the presence of a superficial tracheobronchial inflammation, intact mucosa with no evidence of ulcers, and pseudomembranes or other abnormalities; *Aspergillus* spp. are identified in mucus exudates.[7,8] In contrast, pseudomembranous tracheobronchitis is characterized by significant necrosis of bronchial epithelium and formation of pseudomembranous plaques, which are white, gray, or black in color. These lesions may progress and result in extensive invasion of the large airways; however, in the majority of patients, the depth of invasion does not extend beyond the bronchial cartilage.[7,8] Finally, ulcerative tracheobronchitis is the most aggressive form of IBA and manifests with endobronchial plaques, nodules, or areas of ulceration and necrosis; in addition, the infection may extend to the adjacent pulmonary parenchyma and pulmonary vasculature.[7,8] Late sequelae of ulcerative tracheobronchitis include the formation of excessive granulomatous tissue with resulting bronchial stenosis.

The pseudomembranous form of IBA is typically seen in lung transplant recipients, who accounted for almost 40% of published cases.[6,8] In fact, IBA is the most common infection within 3 months following lung transplantation, whereas IPA tends to occur much later in this patient population. Occasionally, pseudomembranous tracheobronchitis is found in various clinical settings including HSCT, hematologic malignancies, metastatic renal cell carcinoma, COPD, AIDS, systemic lupus erythematosus, metabolic abnormalities including DM, and even in immunocompetent individuals.[1,6] Influenza-associated aspergillosis typically manifests as IBA.[1] Patients may be initially asymptomatic or have symptoms attributed to the underlying illness with negative chest radiographs. However, as the infection progresses, symptoms become more pronounced, including characteristic stridor, resulting in respiratory failure and ultimately death. Persistent stridor in neutropenic or severely immunocompromised patients should raise suspicion for IBA; however this symptom occurs in less than one-quarter of all cases. Importantly, *Aspergillus* galactomannan antigen has limited value in IBA diagnosis as it is positive in only 60% of the cases.[5,6]

The ulcerative form of IBA occurs almost exclusively at the site of bronchial anastomosis in lung transplant recipients.[6] Bronchoscopically, the appearance is that of severe tracheobronchitis with multiple ulcers at the site of anastomosis. The symptoms are similar to those of pseudomembranous IBA. Complications include acute IPA, severe bronchial stenosis, anastomotic dehiscence, and bronchial necrosis with bronchoarterial anastomotic fistula.[6] Rarely, ulcerative IBA develops in patients with AIDS or solid tumors.[6] Diagnosis of all forms of IBA requires a high index of suspicion and is established only by bronchoscopic examination.

Bronchial stump aspergillosis is an unusual complication of lung resection.[6,7] The period from pneumonectomy to the onset of infection usually ranges from 6 to 12 months, although it was noted to occur after 3 years in one case. Patients may present with a productive cough and hemoptysis, sputum that may be putrid, and occasionally, expectoration of fungal material or suture thread.[6,7] Chest radiographs are usually unchanged when compared with those taken at baseline. The cause is secondary *Aspergillus* infection of silk suture material used to close the bronchus after pulmonary resection. Local inflammation, compromised tissue viability, and the use of silk sutures favor the establishment of *Aspergillus* infection. Substitution of nylon monofilament for silk sutures at surgery has significantly reduced this infectious complication.[6,7]

All of the forms of IBA, including bronchial stump anastomosis, require prompt treatment with systemic antifungals for IA (discussed in detail below). Data from controlled studies of the treatment of IBA are lacking, however. A common, although unproven practice is to combine systemic antifungal therapy, such as intravenous AMB-D or voriconazole, with aerosolized AMB-D.[6,7] Notably, most reported failures occurred following cessation of the treatment. Finally, surgical resection and stent placement may be necessary in conjunction with antifungal therapy if dehiscence of the anastomosis occurs because of tracheobronchial aspergillosis.[5–7]

Chronic Pulmonary Aspergillosis

Chronic forms of *Aspergillus* infection of the lung have been increasingly recognized.[8] CPA occurs in patients with chronic cavitary lung disease and is characterized by an indolent clinical course evolving over months to years, constitutional symptoms, serum IgG to *A. fumigatus*, elevated acute phase markers of inflammation, and an underlying immune deregulation that remain largely uncharacterized. Locally invasive (semi-invasive) *Aspergillus* infection may be evident histopathologically. However, both angioinvasion and dissemination are absent. A variety of terms have been used for CPA, including pulmonary aspergillosis with cavitation, complex aspergilloma, chronic granulomatous aspergillosis, semi-invasive pulmonary aspergillosis, and CNPA.[8]

A previously proposed subclassification of CPA based on clinical and radiographic findings included CNPA, chronic cavitary pulmonary aspergillosis (CCPA), and chronic fibrotic pulmonary aspergillosis (CFPA).[8] CNPA is a syndrome of slowly progressive cavitary lung disease, chronic respiratory symptoms, and the presence of precipitating antibodies against *Aspergillus*. Some cases of CNPA have invasion of the lung parenchyma by *Aspergillus* spp. However, in most of the described cases, there is no tissue invasion despite the presence of extensive and progressive tissue damage. CCPA refers to cases in which there is formation and expansion of multiple cavities over time, whereas CFPA refers to cases in which cavity formation is followed by a pronounced fibrotic reaction.[8] In addition, it has been recommended that any case with proven hyphal invasion of tissue should be classified as CNPA. In view of the common underlying immunopathogenesis, CPA is the preferable term used for all the aforementioned clinical entities.

Defects in mucociliary clearance, epithelial integrity, and mucosal immunity associated with structural lung disease appear to be critical factors in the pathogenesis of CPA.[8] Prior mycobacterial lung infection, emphysema and/or COPD, bullae, asthma, sarcoidosis, pneumoconiosis, lung cancer, thoracic surgery, upper lobe fibrosis complicating ankylosing spondylitis, marijuana use, and a history of *Legionella* infection have been described as predisposing conditions for CPA. In addition, chronic inflammation and fibrosis as a result of incompletely understood defects in systemic immune response to *Aspergillus* may play a role in the pathogenesis of CPA. Hence, defects in mannose-binding lectins, alterations in SP-D, certain polymorphisms in cytokine-encoding genes such as transforming growth factor β, TNF-α, IFN-γ, and IL-15, and immunometabolic defects due to corticosteroid-based therapy, diabetes mellitus, AIDS, and alcohol abuse, have all been associated with CPA in humans.[8] However, the precise pathophysiologic mechanism of new cavity formation remains uncertain.

CPA tends to affect middle-aged individuals who are relatively immunocompetent and more male than female individuals.[8] CPA has an indolent and progressive course that lasts for years. Chronic productive cough and weight loss with mild hemoptysis, dyspnea, and fatigue are the usual presenting symptoms. Pleural fibrosis and *Aspergillus* empyema appear to complicate some cases of CPA.[8]

Although the diagnosis of CPA may be suspected with a single chest radiograph, sequential chest radiographs are typically required to confirm the progressive nature of CPA lesions. CT is particularly useful in defining the precise pattern and extent of the disease. Typical radiographic findings include the presence of one or more cavities, which may or may not contain fungus balls, often located in the upper lobes.[8] New cavity formation and expansion of preexisting cavities are also characteristic of CPA. Pericavitary infiltrates and adjacent pleural thickening are frequently observed and appear to correlate with the overall disease activity.[8] With appropriate treatment, these radiographic abnormalities may regress, leaving residual thin-walled empty cavities.

The combination of characteristic clinical and radiologic findings and either the presence of *Aspergillus* precipitins or the isolation of *Aspergillus* spp. from respiratory samples is highly indicative of CPA.[8] Although the demonstration of precipitin or IgG antibodies against *Aspergillus* is the cornerstone and a prerequisite for the diagnosis of CPA, these antibodies may be negative in approximately 10% of CPA patients, especially in case of infection with non-*fumigatus Aspergillus* spp.[8] Histopathology demonstrates chronic inflammation and fibrosis, sometimes with granulomatous features with or without visible hyphae. The absence of hyphae does not exclude the diagnosis of CPA because of the paucity of high fungal burden in patients with CPA.

Differentiating CPA from other serious lung conditions that require specific therapy, such as cancer and chronic cavitary mycobacterial and endemic fungal infections, as well as other inflammatory lung conditions, is a major challenge as overlap is not uncommon. In fact, there is a strong association between CPA and atypical mycobacterial infections. In these cases, imaging is not helpful, so biopsy and comprehensive microbiologic studies must be used to exclude the coexistence of CPA with such entities. In addition, CPA differs from simple aspergilloma because of the presence of constitutional symptoms for at least 3 months, the development of persistent pericystic lung nodules or pleural thickening, consolidations or ground-glass opacities, and the development and/or progression of cavities.[8] Finally, one should always consider the possibility of a pyogenic bacterial infection in a cavity that may require drainage and appropriate antibacterial treatment.

CPA requires prolonged treatment with systemic antifungal agents. In the literature, most patients with CPA have received treatment with oral itraconazole, whereas IV AMB-D has been successfully used in refractory cases.[8] In a series of 18 patients, use of itraconazole capsules resulted in improvement or stabilization of disease in 71% of the cases.[8] Use of voriconazole has been associated with favorable responses in small case series with response rates ranging from 30% to 80% and should be considered as another treatment option. Posaconazole has also been successfully used with a 61% response rate in 79 patients with CPA. However, emerging rates of azole resistance in *Aspergillus* isolates recovered from patients with CPA have been reported, although there is controversy on whether in vitro resistance of *A. fumigatus* to azoles correlates with worse clinical outcome. In addition, serious side effects necessitating discontinuation of treatment with azoles occur in up to 27% of patients. Alternative treatment strategies include intravenous use of polyenes or echinocandins. Although the reported response to IV AMB-D (81%) appears to be slightly better than that to itraconazole, administration of AMB-D may require prolonged hospitalization and is associated with considerable toxicity, especially nephrotoxicity.[8] In a recent randomized study, treatment with IV micafungin had comparable (60%) rates of response with IV voriconazole (51%) and significantly fewer adverse effects in patients with CPA and could represent an alternative especially in cases where azole resistance in a concern.[6] Anecdotal reports of improved outcome as a result of adjunctive immunomodulating treatment with IFN-γ have also been reported based on suboptimal IFN-γ responses in a limited dataset of patients with CPA.[8]

Surgery plays a limited role in the treatment of CPA because of the poor overall lung function in many patients. Major postoperative complications, such as respiratory failure, bronchopleural fistulae, pleural extension of aspergillosis, and even dissemination of *Aspergillus* can occur.[8] Thus, surgery should be reserved for selected patients with a reasonable respiratory reserve for whom there are no other treatment options. For example, surgery may be appropriate for patients with severe hemoptysis if embolization fails.

Although systemic antifungal therapy for CPA seems to be beneficial, assessment of response to it is difficult to gauge because the activity of the disease may fluctuate over time. Weight gain and improved energy levels are the earliest and most reliable indicators of response. Inflammatory markers also improve albeit more slowly, and they usually remain elevated even during long-term therapy. Relapse months or years after discontinuation of treatment is frequently reported. In view of the suboptimal effect of antifungal therapies, understanding molecular immunopathogenesis of CPA is essential for development of host directed therapies.

Invasive Pulmonary Aspergillosis

An important clinical manifestation of *Aspergillus*-related disease is invasive pulmonary aspergillosis, discussed in detail below.

Epidemiology *Aspergillus* has emerged as one of the most common causes of infectious death in severely immunocompromised patients, with mortality rates of 30% to 50% in patients with leukemia and recipients of HSCTs.[1,6,7] Surveillance studies demonstrated a three- to fourfold increase in the frequency of *Aspergillus* infections at major cancer centers after 1990s. In fact, IPA has surpassed invasive candidiasis as the most common fungal infection found at autopsy at several institutions; approximately 15% to 20% of patients with leukemia die of fungal pneumonia caused by *Aspergillus* spp. Similarly, in allogeneic HSCT recipients, 15% to 30% of deaths are caused by refractory fungal infections, mainly caused by *Aspergillus* spp., and most of these infections occur late in the postengraftment period in the setting of graft-versus-host disease (GvHD).[1,6,7] Large prospective multicenter surveillance studies contacted by the Transplant-Associated Infection Surveillance Network (TRANSNET) and Prospective Antifungal Therapy (PATH) Alliance have furthered insights into the epidemiology of IA in the United States. From both studies, IA has emerged as the most common invasive fungal infection in HSCT and solid-organ transplant recipients (43% and 59% of all IFIs, respectively) over invasive candidiasis and mucormycosis, with a 12-month cumulative incidence of 1.6%. Overall mortality in these patients was estimated to be approximately 36% and 75% at 12 weeks and at 1 year, respectively.[6,7]

Changes in HSCT practices over the past decade have greatly impacted the epidemiology of IPA. Autologous HSCT is associated with a low risk of IPA because of shortened periods of pre-engraftment neutropenia and a lack of GvHD. On the other hand, IPA has a bimodal distribution in allogeneic HSCTs, with patients at risk before and after bone marrow engraftment. The increasing use of peripheral blood stem cells, growth factors, and nonmyeloablative conditioning regimens (minitransplants) in allogeneic HSCT has shortened the duration of pre-engraftment neutropenia and the incidence of IPA shortly post HSCT. In contrast, late (40–80 days after engraftment) and very late (80+ days after engraftment) IPA has increased.[6,7] This trend is associated with increased use of matched unrelated-donor (MUD), haploidentical allogeneic transplants and with interrelated risk factors, such as lymphopenia, chronic GvHD, corticosteroid-based therapy, new immunosuppressive regiments, and/or CMV infection.[6,7] Among HSCT recipients, IPA now predominantly occurs as a community-acquired rather as a nosocomial infection in nonneutropenic patients late after engraftment, in whom GvHD and management with increasingly intense immunosuppression have emerged as the major risk factors. Of interest, recent studies in HSCT recipients implicate geoclimatic changes, associated with high environmental spore counts following periods of high temperature and low precipitation, as a factor for the development of IPA.

In addition to the "classic" groups of patients at risk for IPA, such as those with prolonged, profound neutropenia because of a hematologic malignancy (5%–25% risk) or aplastic anemia; recipients of allogeneic HSCTs (5%–30% risk), or lung transplants (17%–26% risk); those with AIDS, severe combined immunodeficiency, or CGD (25%–40% lifetime risk); burn patients; and patients receiving chronic corticosteroids, IPA has been increasingly described in new groups of patients.[6,7] Hence, patients with systemic lupus erythematosus, patients with multiple myeloma who receive high-dose steroids, and premature neonates are prone to the development of severe IPA. Furthermore, IPA is an emerging entity in patients with low-risk malignancies of lymphoid origin, inflammatory diseases, or autoimmune diseases who receive small molecule kinase inhibitors targeting immune signaling pathways. In particular BTK inhibitors are associated with a surge of cases of IPA. IPA is less commonly encountered in patients receiving JAK/STAT signaling, ERK, or multikinase signaling inhibitors.[1] Even the use of high-potency inhaled steroids may predispose some apparently normal hosts to IPA in rare instances. IA is considered an emerging infection in patients with prolonged stay in intensive care units (ICUs) due to immunoparalysis of myeloid phagocytes.[1] ICU aspergillosis is a distinct clinical entity that is probably underreported.[5–7] Influenza associated aspergillosis and aspergillosis associated with macrophage activation due to other viral syndromes (e.g., severe fever and thrombocytopenia syndrome, COVID-19–associated aspergillosis) are emerging clinical entities.[1]

IPA caused by *Aspergillus* spp. less susceptible to antifungals than *Aspergillus fumigatus* such as *A. terreus* and *A. flavus* has also been reported in individual institutions.[1,6,7] This phenomenon may be at least partially a reflection of antifungal selection pressure determined by extensive empirical and prophylactic use of antifungal agents in high-risk patients or evolutional pressure by environmental exposure to azoles. Alternatively, because non-*fumigatus* aspergilli cause nosocomial infections more frequently than does *A. fumigatus*, an epidemiologic niche for these species may also account for their predominance in some institutions. *A. terreus* is clinically resistant to AMB, but species including *A. flavus*, *A.*

lentulus, *A. nidulans*, *A. ustus*, *A. glaucus*, and others, can also demonstrate resistance to antifungal agents.

A number of nosocomial clusters of IPA have been reported over the past three decades mostly associated with hospital construction and defects in air-handling equipment. Air and environmental surfaces have been the focus of most investigations. An outbreak of IPA after major cardiac surgery caused by abnormally high levels of fungal spores in the air of the ICU has been reported.

Pathogenetic Mechanisms Because *Aspergillus* is a saprophytic mold that colonizes in the respiratory tract of immunocompromised patients, the pathogenesis of infection depends on the host's underlying immunometabolic defects in myeloid phagocytes. In the immunocompromised host, IPA typically occurs following inhalation of *Aspergillus* conidia, although hematogenous dissemination from a cutaneous or gastrointestinal source is seen occasionally.[1–3] Damage to respiratory epithelium because of radiation therapy, chemotherapy, GvHD, or prior infection (e.g., RSV, influenza) may facilitate attachment of *Aspergillus* conidia to the respiratory epithelial surface.[1–3] Furthermore, acquired iron overload related to the underlying disease promotes *Aspergillus* invasive fungal growth and likely impairs antifungal effector pathways in phagocytes.[1]

Breach of mucosal host defense mechanisms in the setting of underlying immunodeficiency places the host at risk for invasive infection by *Aspergillus* spp.[1,3,6,7] For example, CMV infection can result in dysfunction of dendritic cells and phagocytes, which may predispose patients to IPA. Of interest, critically ill patients with prolonged ICU stay develop a systemic deactivation of the immune system following sepsis or any severe insult that has activated a systemic inflammatory response.[1–3] This sepsis-induced immune paralysis often results in superinfection with opportunistic pathogens, including *Aspergillus*. In agreement, mice recovering from sepsis remain exquisitely susceptible to *Aspergillus* and develop IPA upon pulmonary infection without the need for immunosuppression.[1–3] Although the mechanism of increased susceptibility to *Aspergillus* in sepsis-induced immunosuppression remains obscure, there is evidence of predominance of a deregulated myeloid cell function induced by cytokine hyporesponsiveness in the lung of mice that develop invasive fungal infection. Importantly, deregulated cytokine release by myeloid cells and associated susceptibility to IPA in septic mice could be restored by adoptive transfer of bone marrow–derived dendritic cells from healthy mice.[1–3]

Once germination of conidia occurs, *Aspergillus* hyphae invade pulmonary arterioles and lung parenchyma, leading to ischemic necrosis. Hematogenous dissemination with thrombosis, hemorrhagic infarction, and invasion of distant organs may result from invasion of arterioles by *Aspergillus* hyphae and is found in approximately one-third of cases of IPA at autopsy.[1,6,7,9,10] Thus, IA, in addition to pneumonia, can present with a clinical picture similar to that of other thrombotic and embolic diseases, such as pulmonary embolism, cerebral vascular accidents, Budd–Chiari syndrome, and renal papillary necrosis. In addition, IA can spread to contiguous structures, across the diaphragm to the stomach, or from the lung to the heart or superior vena cava.

Importantly, it has been recently demonstrated that IPA has different pathophysiologic mechanisms depending on the type of immunosuppression. Thus, a low *Aspergillus* tissue burden, extensive inflammatory injury, absence of angioinvasion, and localized infection have been observed in CGD, sepsis- or corticosteroid-immunosuppressed mice, largely attributed to impaired activation of ROS-dependent activation of autophagic signaling (LAP) regulating fungal killing. In contrast, minimal inflammation, extensive angioinvasive *Aspergillus* growth, and disseminated infection are characteristic of IPA in cyclophosphamide-treated neutropenic mice.[1,6,7] In mice with LAP-defective myeloid phagocytes, host immune effector cells appear to have limited activity against *Aspergillus* hyphae but cause extensive alveolar damage and exudative bronchiolitis, which appears to be more important than the *Aspergillus*-induced injury itself. This nonangioinvasive form of IPA has been increasingly recognized in a wide range of nonneutropenic hosts, including those who received corticosteroids, recipients of solid-organ transplants and allogeneic HSCTs with GvHD, and patients with CGD and immunoparalysis induced by sepsis (Fig. 132-6).[1,6,7] Similar to the animal models of IPA, histopathology in those nonneutropenic patients is characterized by extensive pyogranulomatous inflammatory reactions, inflammatory necrosis, and extensive cavitation.

Studies on genetic susceptibility to IA have been almost exclusively performed in allogenic HSCT. SNPs in PTX-3 in donor hematopoietic cells results in functional defects in phagocytosis and killing of neutrophils and confers increased risk for IA in independent gene association studies. Although deficiency of TLR adaptive protein MyD88 and Dectin-1 in humans is not associated with the development of IA, genetic polymorphisms in donor TLR-1, TLR4, TLR-6, and Dectin-1 predispose to the development of IA in allogenic HSCT recipients.[1–3] In addition, polymorphisms in IL-10 and plasminogen are associated with increased risk for IA. Thus, better understanding immunogenetics of IA in these

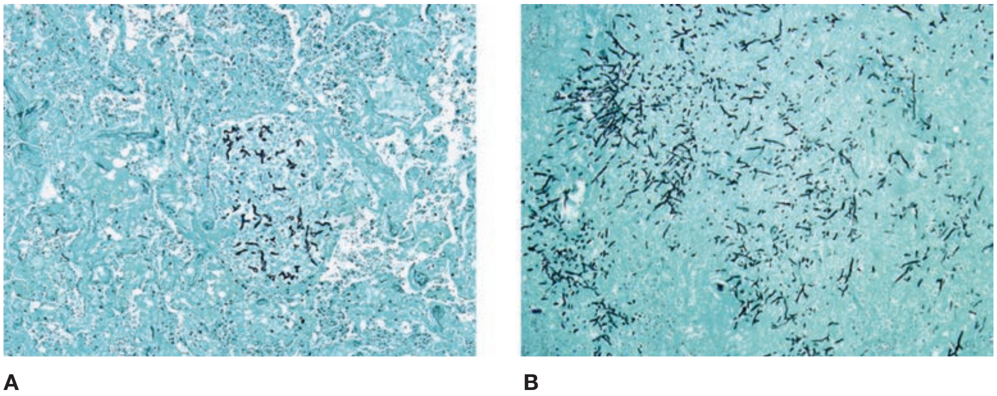

Figure 132-6 The characteristic pattern of *Aspergillus* invasion in tissue obtained from (**A**) an HSCT recipient with IPA and severe GvHD and (**B**) a patient with acute leukemia and severe neutropenia in whom IPA developed. Extensive inflammation, less *Aspergillus* burden, and absence of angioinvasion was observed in the patient with GvHD. In comparison, the histopathology of IPA in the patient with severe neutropenia was characteristic for scant infiltration by phagocytic cells, extensive coagulative tissue necrosis caused by angioinvasion, and a high fungal burden. high-risk individuals could facilitate risk stratification and design of preventive strategies.[1–3]

Clinical Features Symptoms of IPA are subtle and atypical and occur relatively late in the disease course. IPA symptoms begin with low-grade fever (unless the patient is receiving corticosteroids), which may be followed by a mild nonproductive cough suggestive of bronchitis. Pleuritic chest pain and progression to pneumonia occur within 1 to 2 days. Cavitation tends to occur in patients if immunosuppression is decreased, such as in leukemic patients during recovery of bone marrow hematopoiesis or when steroid-based therapy is reduced significantly, and on occasion gives rise to massive hemoptysis (Figs. 132-7 and 132-8).[1,6,7] Pleuritic pain and slight hemoptysis may suggest pulmonary infarction. Patients may also expectorate necrotic tissue filled with hyphae. Cough, sputum production, and pleural effusion are either absent or minimal. IA must be strongly considered when dealing with susceptible patients in whom treatment with broad-spectrum antibiotics fails.

Extrapulmonary sites may be involved including the highly vascular organs such as the kidneys, liver, spleen, and central nervous system. Invasive disease of the nose and paranasal sinuses occurs in immunocompromised patients, and contiguous invasive spread into the orbit or into the cranial vault can result in a syndrome similar to rhinocerebral mucormycosis.

Diagnosis Substantial delay in establishing an early diagnosis remains a major impediment to the successful treatment of IPA. Chest radiographs are not sensitive in detecting early forms of bronchopulmonary IPA, and up to 10% of patients with proven IPA have "normal" chest radiographs within a week of death.[1,6,7] High-resolution CT scans of the chest may reveal small wedge-shaped subpleural lesions or nodules typically surrounded by intermediate attenuation. This halo sign correlates with hemorrhage and edema surrounding an infarct caused by thrombosis and is highly suggestive of acute IPA, especially in neutropenic patients with leukemia.[1,6,7] However, the halo sign has been documented only in 33% to 60% of patients and is transient. In fact, to be useful for the diagnosis of IA, CT must be performed within 5 days of the onset of infection, because more than 75% of initial halo signs disappear within a week.[1,7,9] With neutrophil recovery, these lesions coalesce and cavitate, forming the "air crescent" sign, a classic sign of late filamentous invasive mold infection (IMI). However, the air crescent sign does not appear until the third week of the infection, and the appearance may be too delayed to be helpful in the diagnosis of IA. Importantly, lesions frequently increase in size in the first 7 to 10 days following effective antifungal therapy. In view of the angioinvasive nature of IPA, detection of vascular occlusion by CT-based pulmonary angiography was evaluated in a recent study as an early sign of IMI. Importantly, the presence of positive vascular occlusion sign was more sensitive and specific than the halo sign and comparable to serum galactomannan test for diagnosis of IPA. Thus, CT pulmonary angiography could represent a viable diagnostic tool for IPA, especially in patients at low-risk of contrast-induced acute kidney injury.

Persistently febrile neutropenic patients with leukemia would benefit from the use of early high-resolution chest CT to identify early radiologic signs of IPA such as the halo sign. In a study of febrile neutropenic patients, early and routine CT scanning coupled with early intensive antifungal-based treatment and surgery resulted in increased survival rates when compared with therapy initiated at the first sign of a pulmonary fungal infection.[1,6] CT also plays a critical role in determining the appropriateness of various downstream diagnostic procedures (bronchoalveolar lavage [BAL], percutaneous needle biopsy, and open lung biopsy) in patients with IPA. Nonetheless, clinical and radiologic presentations of IPA in the expanding group of nonneutropenic patients who develop infection is atypical, including cases with tree-in-bud opacities or diffuse ground-glass appearance and ARDS-like features in CT.[1,6–9] Development of novel imaging platforms based on antibody-guided positron emission tomography and magnetic resonance (immunoPET/MR) for early and specific detection of *Aspergillus* invasive growth holds promise as a future diagnostic modality for IPA.[1]

Respiratory cultures of *Aspergillus* from expectorated sputum, bronchial washings, or BAL specimens have low sensitivity (<30%) for diagnosing IA but a high positive predictive value (>60%) in heavily immunocompromised patients.[6] Early performance of CT-guided fiberoptic bronchoscopy with BAL in immunocompromised patients with pulmonary infiltrates has been shown to improve the diagnostic yield of this procedure. In addition, there is a need for the development of standardized BAL protocols in order to facilitate comparative clinical studies on the diagnosis of IPA. Blood cultures have little diagnostic value for IA but may reflect true disease cases of *A. terreus* infection. Ultimately, open lung biopsy may be required for a definitive diagnosis of IPA and may not be feasible until late in the course of infection or recovery of pancytopenia.

In recent years, efforts have been directed toward identifying non-culture-based markers for rapid, reliable diagnosis of IA.[9] Detection of anti-*Aspergillus* antibodies has very poor sensitivity for IA, especially in patients receiving immunosuppressive agents. Instead, tests based on identifying circulating polysaccharides, peptides, nucleic acids or metabolites released during fungal growth are promising.[1] To date, the two approaches that have demonstrated the greatest promise in early clinical studies are detection of antigens and measurement of *Aspergillus* nucleic acids by using PCR.

Galactomannan is a polysaccharide cell wall component of *Aspergillus* spp. that is released into the circulation during fungal growth in tissues and can be detected in the serum, BAL, and other fluids of patients with IA.[1,6,7,9] A sandwich enzyme-linked immunosorbent assay (ELISA) capable of detecting galactomannan at concentrations as low as 0.5 ng/mL is the most widely used assay for diagnosis of IPA. Initial studies evaluating the role of galactomannan serum assay in the diagnosis of IA have been predominantly conducted with profoundly neutropenic patients undergoing chemotherapy for cancer or recipients of HSCTs who were on fluconazole prophylaxis. These studies have documented sensitivity rates ranging from 67% to 100% and specificity rates ranging from 86% to 99% in these patients.[1,9] When serially monitored, the galactomannan assay preceded the diagnosis of IA by an average of 6 to 14 days and has prognostic value in response to therapy.[1,9] However, in a study that evaluated the value of the galactomannan assay in the detection of early IA, the appearance of major lesions (halo sign, air crescent sign, and cavitation) on high-resolution CT scans almost coincided with or even preceded the detection of the galactomannan antigen in serum.[6,7] Furthermore, the performance of serum GM assay is substantially compromised in other settings, including breakthrough IA to mold-active antifungal prophylaxis, pediatric populations, solid-organ transplant recipients, and other nonneutropenic patients with IPA characterized by deregulated inflammation and low fungal burden.[7] Other factors, such as the pretest probability of infection, the patient's immune status (neutropenia vs. GvHD), antifungal therapy, antibacterials, and diet may affect both the performance and interpretation of the galactomannan assay. Hence, sensitivity rates as low as 30% have been reported in nonneutropenic HSCT recipients receiving mold-active antifungal prophylaxis and lung transplant recipients.[6,7,9] In addition, false-positive results have been described in patients receiving β-lactam antibiotics, particularly piperacillin–tazobactam, as well as in those ingesting certain cereals, pastas, nutritional supplements, and soy sauce produced with fermentation products of *Aspergillus oryzae*, a fungus commonly used in food production.[6,7,9] In addition, false-positive galactomannan antigenemia has also been reported as a result of transfusion of blood products. BAL GM has substantially improved diagnostic yield compared to serum GM and is the preferably diagnostic method in high-risk patients with IPA.[9] A meta-analysis of 30 diagnostic studies with the use of BAL GM, using an optimal cutoff value of 1.0, the BAL-GM assay had 90% sensitivity and performed better compared to PCR and serum GM test although specificity was lower (89%).[1,9] Point-of-care GM detection with lateral flow device shows comparative performance with GM ELISA and holds promise as an alternative diagnostic modality especially in resource limited settings.[1,9]

A colorimetric commercially available assay that allows for batch (>20 samples) detection of 1,3-β-D-glucan in patient samples, an integral cell wall component in a number of pathogenic yeasts and filamentous fungi, has been recently endorsed in guidelines as an alternative to GM for diagnosis of IPA.[9] The sensitivity and specificity rates for this test in limited studies thus far have ranged from 67% to 100% and from 84% to 100%, respectively. Several false-positive test results have been reported in patients with cirrhosis; in patients undergoing hemodialysis, albumin infusion, or receipt of blood products; in patients following abdominal surgery; with the use of surgical gauze products; and in those receiving antimicrobials or chemotherapy with particular agents.[9] Furthermore, the 1,3-β-D-glucan assay has been reported to be less sensitive and reproducible and to become positive later in the course of IA when compared with galactomannan antigen assay. The release of a rapid test that allows for single testing of 1,3-β-D-glucan will facilitate broader use of this assay for diagnosis of IPA.[1,9]

PCR detection of *Aspergillus* nucleic acids has been recently implemented in updated guidelines for diagnosis of IA.[9] The sensitivity of PCR is excellent, but its specificity for invasive infections can be problematic, and false-positive results are common. Multiple unresolved issues accompany the use of PCR for the diagnosis of IA, including the sample type (serum, BAL fluid), amplification strategy (nested vs. conventional PCR), protocol (real-time quantitative vs. conventional PCR), primer selection (*Aspergillus*-specific or pan-mold, pan-fungal primers), method of DNA extraction, and CT cutoff values.[1,9] A meta-analysis of 19 studies comparing the value of BAL PCR with BAL GM concluded that although sensitivity and specificity of both tests were comparable, combination of both tests increased sensitivity without compromising specificity. Thus, like GM testing, PCR is likely to become an adjunctive diagnostic method alone or in combination with other biomarkers and standard microbiologic, histologic, and radiographic methods of diagnosing IA.

Novel investigational diagnostic approaches include the development of a breath test to detect volatile *Aspergillus* biomarkers that are not produced by other pathogens, and detection of circulating *Aspergillus* antigens in BAL and serum of patients with IPA by using an immunochromatographic lateral flow device.

Treatment of IPA Although the past two decades have witnessed improved outcomes of patients with IA, the mortality rate of this mycosis in severely immunocompromised patients remains high.[6] Several strategies have been applied in an attempt to improve the outcome of IA. These include the introduction of potent antifungal agents such as voriconazole and other newer triazoles, early onset of treatment triggered by CT and/or galactomannan antigen, use of delivery systems to improve the therapeutic index of currently available antifungals such as lipid formulations of AMB, and possibly combination antifungal therapy, surgical excision of sequestered necrotic lesions, and use of immunomodulating agents in selected patients.[6] There has not been a systemic evaluation of the merit of each of these strategies in the treatment of IA, however. This is not surprising in view of the complexity of IA and the paucity of organized, prospective controlled clinical studies in refractory IA.

Tables 132-5 and 132-6 list the principles of management of IPA. Until the early 1990s, AMB-D was the only drug available for the treatment of aspergillosis, and no prospective evaluations of this drug had been attempted.[6] Another major obstacle to evaluating the merit of antifungal therapy for IPA until the early 2000s was difficulty in establishing the diagnosis; hence, most patients received empiric treatment. The introduction of uniform diagnostic criteria for proven, probable, and possible IA by the European Organization

TABLE 132-5 Therapeutic Options for Invasive Fungal Infections

Regimen	Advantages	Disadvantages
Amphotericin B-deoxycholate (AMB-D)	Broad-spectrum activity, lack of frequent resistance, fungicidal activity, lower cost	Acute and chronic toxic effects, minimally effective in patients with neutropenia and with chronic disseminated candidiasis, intravenous preparations only
Lipid formulations of AMB	Broad-spectrum activity, reduced nephrotoxicity, increased doses can be administered	Only prospective randomized trial showed no advantage in efficacy over AMB-D despite higher doses, more expensive, intravenous preparations only
Fluconazole	Oral and intravenous preparation, as effective as AMB in randomized trials of nonneutropenic individuals with candidiasis, minimal toxicity, more effective for chronic disseminated candidiasis, little experience in neutropenic patients but appears to be as effective as AMB	Variable activity against *C. glabrata* and *Candida dubliniensis*, inactive against *C. krusei*, some drug–drug interactions, inactive against molds
Itraconazole	Broad spectrum of activity, lower cost, oral, and intravenous preparations	Drug–drug interactions and poor absorption (capsules) are common causes of clinical resistance, marked interpatient variability in serum levels, expensive
Voriconazole	Oral and intravenous preparations; broad-spectrum activity, including fluconazole-resistant species (e.g., *C. krusei*); fungicidal against *Aspergillus*	Drug–drug interactions, erratic pharmacodynamics, more expensive than fluconazole, inactive against *Zygomycetes*, some cross-resistance with fluconazole, need for drug level monitoring, expensive
Posaconazole	Oral and intravenous formulations; slow-release tablets show improved absorption and PK properties; broadest spectrum of activity among all azoles, including *Candida* spp., *Aspergillus*, *Mucorales* spp., and most other filamentous fungi	Drug–drug interactions, poor absorption, no intravenous formulation available yet (under development, in clinical trials), some cross-resistance with itraconazole, need for drug level monitoring, expensive
Isavuconazole	Broad spectrum of activity, including *Candida* spp., *Aspergillus* spp. and *Mucorales*. Cases of breakthrough IFIs especially in the setting of protracted neutropenia.	Excellent absorption and tolerability, fewer drug–drug interactions, predictable pharmacokinetics, less need for drug level monitoring
Echinocandins (caspofungin, micafungin, anidulafungin)	Fungicidal activity against most *Candida* spp., minimal toxicity, lack of cross-resistance with azoles, preferred regiment for candidemia, immune-modulating properties	No oral preparation, poor central nervous system and urinary penetration, narrow spectrum of activity (*Candida, Aspergillus*), limited experience in neutropenic patients
Flucytosine	Synergistic with AMB and fluconazole, combination of flucytosine and AMB may be superior to AMB alone for chronic disseminated candidiasis and *C. tropicalis* infection	No IV preparation, causes myelosuppression, often requires monitoring of serum concentrations, emergence of resistance in monotherapy

TABLE 132-6 Drug Dosages for Serious Invasive Fungal Infections of the Lung

Drug	Loading Dose	Daily Dose	Route
Amphotericin B deoxycholate (AMB-D)	—	1.0–1.5 mg/kg	IV only
Lipid AMB	—	3–5 mg/kg	IV only
Fluconazole	800 mg (12 mg/kg)	400 mg (6 mg/kg)	IV, PO
IV itraconazole	200 mg bid ×2 d	200 mg	IV
Itraconazole solution	200 mg bid × 2 d	200 mg	PO
Itraconazole caps	200 mg tid × 3 d	200 mg bid	PO
IV voriconazole	6 mg/kg bid × 2 d	4 g/kg q 12 h	IV
Voriconazole tab	—	200 mg q 12 h (≥40/kg)^{a} 100 mg q 12 h (<40/kg)	PO
Posaconazole solution	200 mg qid × 7 d	400 mg bid	PO
Posaconazole tablets	300 mg bid × 1 d	300 mg	PO
IV Posaconazole	300 mg bid × 1 d	300 mg	IV
Isavuconazole	200 mg tid × 2 d	200 mg	PO, IV
Caspofungin	70 mg	50–70 mg	IV
Micafungin	150 mg	100–150 mg	IV
Anidulafungin	200 mg	100 mg	IV

bid, twice a day; caps, capsule; d, day; h, hours; IV, intravenous; PO, oral; q, every; sol, solution; tab, tablet; tid, three times a day.

[a] *Oral daily dose may be increased up to 300 mg bid (≥40/kg) or 150 mg bid (<40 kg).*

for Research and Treatment of Cancer (EORTC)/Mycoses Study Group (MSG) consortium has been an advance.[9] These criteria are standardized and reproducible and consist of host-risk, microbiologic, clinical/radiologic, PCR, and/or galactomannan antigen criteria. Despite the fact that the EORTC/MSG criteria have been updated to incorporate biomarkers for the diagnosis of IMI, their clinical applicability was questioned in real word settings; for example, in an autopsy study more than 60% of proven cases of IA in patients with hematologic malignancies were not identified antemortem according standard definitions.[10]

The introduction of the broad-spectrum triazole voriconazole represents a major therapeutic advance in the management of IA, including IPA.[6,7] Voriconazole is available in both intravenous and oral preparations and is much better tolerated than AMB-D. In a large prospective randomized trial comparing voriconazole with AMB-D in patients with definite or probable aspergillosis, the response rate was 53% and 32%, respectively, and the survival rate at 12 weeks was 71% and 58%, respectively.[11] Improved response was seen irrespective of the underlying condition, site of infection, and presence or absence of neutropenia. Patients in whom initial therapy failed received other medications; this occurred more frequently among the AMB-D population primarily because of drug toxicity. The improved survival observed in this comparative study made voriconazole the preferred drug for first-line therapy for IA, and this has been endorsed by many guidelines. A recent study has shown that isavuconazole, a newer-broad spectrum triazole, is equally efficacious and better tolerated than voriconazole.[1] Based on this study, both isavuconazole and voriconazole have an IA indication in the management of IA. Posaconazole, a triazole with broad-spectrum activity against *Aspergillus* and other molds, is endorsed as an alternative therapeutic option in IA guidelines. An interim analysis of a recent randomized controlled study demonstrated that posaconazole was noninferior to voriconazole in terms of all-cause mortality up until day 42 in patients with documented or probable IA and was associated with a better toxicity profile.[12] This new evidence justifies the use of posaconazole as frontline therapy for IPA.

Use of lipid formulations of AMB is an attractive alternative to AMB-D because of reduced nephrotoxicity.[6,7] Although no comparative trials between the lipid formulations of AMB have been conducted thus far, they appear to be equally efficacious, although both toxic effects and costs differ. Most of the available data have been derived from indirect comparisons and suggest that all lipid formulations of AMB, when given at the standard dosage of 5 mg/kg, appear to have efficacy comparable to voriconazole.[6,7] That higher dosages of L-AMB are not necessarily equivalent to greater response rate was demonstrated in a prospective randomized study that compared two different dosages of L-AMB (3 mg/kg/d and 10 mg/kg/d) for the primary treatment of proven and probable IA in 201 patients. Importantly, survival rates and overall response rates were similar among the two study groups; however, higher dosage of L-AMB was associated with greater toxicity.[13] The dose–response relationships for ABLC and ABCD have not been well studied.

The echinocandins, including caspofungin, micafungin, and anidulafungin, belong to a new class of antifungal agents that inhibit the synthesis of 1,3-β-D-glucan, an essential component of the cell wall of many fungi.[6,7] They are all available only in intravenous preparations. In addition, caspofungin and micafungin have been used as primary therapy in noncomparative studies of IA with response rates ranging from 33% to 60% for caspofungin and 50% to 71% for micafungin. In addition, use of caspofungin as salvage therapy has been associated with response rates in 45% (37/83) of patients, including 50% of patients with IPA.[6,7]

Combination Treatment The introduction of echinocandins, a class of antifungal agents with different mechanism of action, reinforced the concept of combination therapy (e.g., azoles plus echinocandins, AMB plus echinocandins, AMB plus azoles and echinocandins) as a possible means to improve suboptimal long-term survival of high-risk patients with IA treated with monotherapy.[14] Many in vitro studies and animal models suggest that administration of an echinocandin with voriconazole may result in additive or synergistic effects, which can potentially translate into clinical benefits. This hypothesis has been supported by small clinical studies and noncomparative observations. A completed double-blind randomized clinical study in 454 patients with IA compared the efficacy of combination of voriconazole and anidulafungin versus voriconazole monotherapy with 6 weeks survival being the primary study endpoint. Importantly, treatment of IA with the combination of voriconazole and anidulafungin was associated with a clinically meaningful survival benefit in patients with hematological malignancies or after HSCT, particularly in patients with a diagnosis of IA based on GM antigen positivity and consistent radiologic findings (6 weeks mortality 15.7% for combination and 27.3% for monotherapy; $p = 0.04$).[1,6] This is the first study to demonstrate a significant impact of combination therapy in the outcome of patients with IA and a positive galactomannan assay.

In another randomized study, the efficacy of L-AMB standard dose (3 mg/kg/d) in combination with caspofungin was compared with L-AMB high dose (10 mg/kg/d) in 30 patients with hematologic malignancies and IPA.[15] The combination of caspofungin plus L-AMB demonstrated higher overall responses rates when compared with L-AMB monotherapy and 100% survival at the end of the study, although differences in responses were not statistically significant, probably because of the small size of the study.

Therapeutic Drug Monitoring A growing body of evidence suggests patient-to-patient variability in the pharmacokinetics of triazoles used for treatment or prophylaxis in IA.[6] Absorption issues (for itraconazole and posaconazole), drug–drug interactions (for all triazoles, especially voriconazole), and pharmacogenetic differences (for voriconazole) may have significant impact in the management and outcome of patients with IA under triazole treatment. Thus, plasma drug level monitoring play an increasingly important role in optimizing the safety (for voriconazole) and efficacy (for itraconazole, posaconazole, and voriconazole) of antifungals with significant interpatient pharmacokinetic variability. Isavuconazole has predictable pharmacokinetics over other triazoles, which might obviate the need for TDM.[1,6] The need to perform therapeutic drug monitoring should be individualized as determined by the clinical status of the host (e.g., specific organ function, comorbidities, and receipt of concomitant medications) and the overall treatment plans.[6]

Surgery The role of adjunctive surgery in the management of IPA also has not been demonstrated conclusively. Pulmonary infarcts and tissue sequestration are common causes of antifungal therapy failure and fatal hemorrhage in patients with IPA. Resection of infected pulmonary tissue is beneficial for selected patients.[6] Residual cavitary lesions, especially when containing fungus balls, after successful antifungal therapy may cause late exsanguinating hemorrhage or reactivation of infection during subsequent myelosuppressive chemotherapy. Removal of these lesions, if surgically feasible, should be considered and may provide survival benefit. Surgical intervention may be a life-saving procedure for patients with IPA who experience acute pulmonary hemorrhage, when performed early in the disease process. It is less evident whether early removal of well-circumscribed lesions close to pulmonary arteries is beneficial. Likewise, the value of late debulking of a pulmonary mass if the patient has multiple fungal lesions that cannot be completely resected is uncertain. Recent uncontrolled data suggest that resection of the lobe most adversely affected by IA is beneficial in treating pulmonary lesions that worsen despite the use of intense antifungal therapy.[6]

Immune Augmentation Treatment Because host immunodeficiency is the critical determinant of the outcome of IA, a large number of studies, mostly preclinical, over the past two decades have focused on strategies to augment cellular immune defenses against IMIs. The available preclinical data suggest that quantitative and qualitative deficiencies in host cellular immune responses can be corrected with adjunctive cytokine therapy, such as the use of myeloid growth factors (e.g., granulocyte colony–stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]), IFN-γ, or a combination of these cytokines plus infusion of host effector cells (e.g., IFN-γ plus granulocyte transfusions), reversal of the underlying immune defects with checkpoint inhibitors, administration of *Aspergillus*-specific T cells or NK cells or engineered fungal-specific CAR T cells.[1,6,7] Granulocyte transfusion therapy has become more feasible since the introduction of G-CSF/corticosteroid mobilization into the donor leukocyte collection process.[6] Currently, there are no data from randomized clinical trials examining the efficacy of granulocyte transfusions for IA or other serious infections during neutropenia. Future studies in this area will likely examine the use of vaccinations and/or cellular transfer with or without adjunctive cytokines to enhance cellular immunity tailored to the underlying immune defects of the individual patient. Importantly, WBC transfusions have been occasionally associated with serious adverse reactions including transfusion-related acute lung injury (TRALI). Clearly, this is a challenging area of investigation. Carefully designed clinical trials will be required to verify results from animal models and other preclinical observations and evaluate both the efficacy and safety of these interventions. Understanding the immunopathogenesis features and underlying host immune defects in the diverse and expanding group of nonneutropenic patients with IPA is essential to design host directed effective immunomodulatory therapies.

Prophylaxis in High-risk Patients Reports on nosocomial outbreaks of IPA have linked cases to hospital construction, the absence of appropriate barriers between patients and the environment, and the presence of fungal spores in room air samples. Specialized air-handling systems such as high-efficiency particulate air (HEPA) filtration with or without laminar airflow ventilation have proved to be effective at excluding *Aspergillus* spores.[1,6,7] However, HEPA filters have not been shown to prevent *Aspergillus* infections during building renovation and may not prevent outbreaks of these infections related to building demolition or renovation. A meta-analysis of 16 controlled trials that evaluated the effect of HEPA filtration on neutropenic patients with hematologic malignancies or HSCT found that the placement of patients in protective environments appeared to be beneficial in preventing IFIs, but the data seemed insufficient to support firm conclusions. The Centers for Disease Control and Prevention guidelines for preventing opportunistic IMIs in allogeneic HSCT recipients recommend the use of HEPA filters in patient rooms (*www.cdc.gov/infectioncontrol/guidelines/isolation/*). However, highly immunocompromised stem cell transplant recipients are commonly managed as outpatients, where engineering standards of the inpatient protected environment are not feasible. More recently, hospital water systems have been implicated as potential sources of high-level spore bursts of pathogenic fungi. During bathroom activities such as showering and toilet flushing, patients may create aerosolized mists of fungal spores that increase the risk of IPA. In addition, researchers reported an association between molds (*Aspergillus* and *Fusarium* spp.) cultured on hospital sinks and water sources and IMIs in patients with leukemia.[6,7] As a result, some have recommended cleaning of patient showers and bathroom areas with a phenolic cleaning solution prior to use by severely immunocompromised patients. Although these preliminary data are intriguing, establishing a causal link between nosocomial exposure to *Aspergillus* spores and subsequent development of IA remains difficult and requires the demonstration of genetic relatedness of environmental *Aspergillus* strains and clinical isolates. In fact, one of the largest molecular epidemiologic studies of IA suggested that any *Aspergillus* strain could be pathogenic in the appropriate host background and that isolates causing invasive disease are not necessarily nosocomially derived.[1,6]

The new oral, extended-spectrum triazoles, such as voriconazole and posaconazole, have a satisfactory pharmacokinetic profile and documented efficacy in the treatment of infections, which may make them suitable for prophylaxis in HSCT recipients and neutropenic patients. Posaconazole has been endorsed by several guidelines as the prophylactic azole of choice. Antifungal prophylaxis with the echinocandin micafungin in HSCT recipients was shown to reduce the incidence of IA;[6,7] however, the fact that echinocandins are parenteral drugs limits use in extended antifungal prophylaxis during the postengraftment period, when IA is most likely to occur.

Secondary Prophylaxis Patients with a history of IA are at high risk of reactivation of the infection if they undergo further intensive chemotherapy or HSCT, with relapse rates up to 30% to 50%. Patients receiving prophylaxis have fewer relapses than do those who do not.[6,7] In an open-label noncomparative study in 45 high-risk HSCT recipients with a previous history of invasive fungal infection (mostly IA), secondary voriconazole prophylaxis resulted in 6.7% incidence of relapse rate of IFI, which is considered lower than the relapse rate reported in historic control studies. Thus, in the absence of comparative clinical trials, triazoles such as voriconazole seem to be the most appropriate agents for secondary prophylaxis.

PULMONARY CANDIDIASIS

Candida, a commensal fungus of mucosal surfaces, is the predominant fungal pathogen in humans. The spectrum of *Candida*-induced illnesses is broad, ranging from mild, chronic mucocutaneous infections to life-threatening acute invasive infections involving potentially any organ.[16] Pulmonary candidiasis is an infrequent form of invasive *Candida* infection that almost exclusively occurs in cases of aspiration pneumonia in immunocompromised patients who have heavy colonization of *Candida* spp. in the oral cavity (primary *Candida* pneumonia) or as part of disseminated candidiasis primarily in neutropenic patients.[16–19]

Candida pneumonia is a challenging infection because of a lack of established, reliable clinical criteria for making the diagnosis. *Candida* is frequently an asymptomatic colonizer, particularly among debilitated individuals who are receiving antibacterials.[16–19] Thus, cultures of sputum and/or BAL that are positive for *Candida* in a patient with a pulmonary infiltrate do not establish the diagnosis of *Candida* pneumonia. An autopsy study of patients with cancer demonstrated that whereas many high-risk patients with pneumonia had *Candida* spp. cultured from sputum and BAL specimens, the specificity (57%–60%) and positive predictive value (29%–42%) of cultures of both types of specimens were low.[16] Similarly, quantitative cultures of transbronchial lung biopsy samples in critically ill, mechanically ventilated patients have been of no predictive value for *Candida* pneumonia.[17] Therefore, only histopathologic demonstration of yeast cells or pseudohyphae in lung tissue is confirmatory of *Candida* pneumonia, which is often impossible to achieve in many patients. Of interest, in a large prospective autopsy study including 233 ICU patients there was no evidence of *Candida* pneumonia despite frequent isolation of *Candida* from the airways.[19] However, *Candida* airway colonization resulted in impaired macrophage effector function in a rat model of *Pseudomonas pneumonia* and has been associated with increased risk for ventilator associated pneumonia by MDR bacteria and overall worse clinical outcome. A recent meta-analysis also found a significant association of *Candida* airway colonization with higher mortality rates and longer ICU stay in patients with VAP. However, it is still unclear whether *Candida* colonization is causally related to poor outcomes or whether it is a marker of underlying host immunosuppression, and there are no studies to justify antifungal treatment for this entity.

Epidemiology

The true incidence of *Candida* pneumonia is unknown, and most of the data on this infection are extrapolated from autopsy series. The fact that only 55 patients with unequivocal evidence of primary *Candida* pneumonia had been reported in the literature up to 1993 emphasizes the rarity of this infection.[17] Large autopsy surveys in patients with cancer reported a prevalence of primary *Candida* pneumonia ranging from 0.2% to 0.4%.[18–21] In another autopsy study that included a general population of patients, primary *Candida* pneumonia accounted for 17% of all *Candida* infections, with an overall prevalence of 0.3%.[21] On the other hand, primary *Candida* pneumonia has been a relatively frequent finding in autopsy studies of high-risk patients, such as premature neonates (1%) and critically ill, mechanically ventilated patients (8%).[17]

In contrast with primary *Candida* pneumonia, secondary lung involvement by *Candida* spp. is a common finding at autopsy, occurring in 42% to 81% of cases of disseminated candidiasis.[18–21] However, the clinical significance of *Candida* pneumonia identified at autopsy, especially in cases of hematogenous dissemination, has been questioned. For example, a study demonstrated that almost half of such *Candida* infections were incidental autopsy findings without clinical significance.[21]

Although large surveillance studies to capture the prevalence of *Candida* pneumonia are lacking, *Candida* was the third most common fungal pathogen after *Aspergillus* and *Cryptococcus* in a series of 140 patients with biopsy-proven invasive fungal pneumonia.[20] Interestingly, an increasing number of patients with primary *Candida* pneumonia were reported during the last years of the study. However, whether these latter cases represented a true increase in the incidence of *Candida* pneumonia or simply reflected a bias because of improved diagnosis is not certain.

Mycology

Similar to the other forms of invasive candidiasis, *Candida albicans* is the predominant species in patients with primary *Candida* pneumonia, accounting for 40% to 70% of all reported cases.[18–21] Until the early 1990s, *Candida tropicalis* and *Candida parapsilosis* were the most common non-*albicans Candida* spp. in patients with primary *Candida* pneumonia. However, the widespread use of broad-spectrum azole antifungals in the 2000s has led to the emergence of less susceptible non-*albicans Candida* spp., such as *Candida glabrata* and *Candida krusei*, as important causes of *Candida* pneumonia. Hence, *C. glabrata* is currently considered the second most common *Candida* spp. in cases of primary *Candida* pneumonia in immunocompromised individuals.[17–20] In cases of secondary *Candida* pneumonia caused by hematogenous dissemination, the distribution of the species appears to follow that in bloodstream candidiasis, with *C. albicans* being the predominant species followed by *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*.[18–21] Recently, sporadic cases of aspiration pneumonia by the emerging MDR *C. auris*, a species with unique epidemiologic properties that can cause outbreaks in healthcare settings, have been reported.

Pathogenesis

Most of the data on the pathogenesis of *Candida* pneumonia have been gained from analysis of histopathologic findings at autopsy and studies of animal models of aspiration-induced pneumonia. *Candida* pneumonia develops only rarely in normal hosts, and most of the reported cases of this infection occurred in heavily colonized, immunocompromised individuals. A constellation of factors suggests that primary *Candida* pneumonia has a distinct pathophysiology when compared with other forms of invasive candidiasis and develops in a particular clinical scenario.[17,18] Specifically, the mechanism of entry of *Candida* into the lungs is via aspiration of oropharyngeal contents.[18] In addition, several studies indicated that the typical risk factors for invasive candidiasis, such as chemotherapy-induced neutropenia, prolonged corticosteroid use, immunosuppressive agent use, prior antibiotic use, hyperalimentation, diabetes mellitus, and the presence of vascular devices were not significantly associated with the development of *Candida* pneumonia.[17–21] In contrast, alteration of mental status (with or without subsequent aspiration) was the most important contributing factor in the majority of these patients. Thus, individuals prone to aspiration who have heavy oral colonization with *Candida* spp., such as those with head and neck cancer receiving chemoradiation, premature neonates, and critically ill, mechanically ventilated patients, constitute the population at highest risk for primary *Candida* pneumonia.

However, a distinct type of secondary *Candida* pneumonia caused by hematogenous dissemination has been described occasionally in profoundly neutropenic patients with cancer.[18] The histopathologic characteristics of *Candida* lesions reflect pulmonary seeding from systemic bloodstream infections. Specifically, autopsy examination of these patients found evidence of pneumonia with scant inflammation and clumps of *Candida* yeast cells and pseudohyphae present in large portions of the involved lung sections in a pattern that closely resembled *Candida* growth in culture medium. Furthermore, in contrast with primary *Candida* pneumonia, destruction of lung parenchyma is subtle, whereas hemorrhage and angioinvasion by pseudohyphae are prominent. Although speculating that typical risk factors for disseminated candidiasis may apply in cases of secondary *Candida* pneumonia is reasonable, the majority of cases of clinically significant infection have been described in profoundly neutropenic patients with leukemia.[18–22]

Clinical Manifestations

The clinical manifestations of primary *Candida* pneumonia are nonspecific and include persistent fever and tachypnea.[16,17] Chest pain, cough, and sputum production occur occasionally. Also, physical examination and routine laboratory studies are nonspecific. Chest radiographs may demonstrate a local or diffuse infiltrate involving one or both lungs, which is most often associated with infection acquired by the endobronchial route. A miliary–nodular pattern is most often associated with hematogenous seeding of the lung in cases of disseminated candidiasis and often appears late in the clinical course of the disease (Fig. 132-9).[16–18]

Extrapulmonary manifestations such as skin lesions, myositis, and endophthalmitis may be the first signs of *Candida* fungemia. Multiple organ involvement prior to or concurrent with pulmonary findings, particularly liver or kidney dysfunction and myocardial failure, may indicate hematogenous seeding that warrants investigation.

Lung transplant recipients occasionally develop an early (within 2 weeks after transplantation) and fulminant *Candida* pneumonia.[17] This association is probably caused by occult aspiration of *Candida* colonizing the donor lung followed by invasive pulmonary *Candida* infection after transplantation when immunosuppression is most intense.

Asthma related to an IgE-mediated allergy to *C. albicans* or allergic bronchopulmonary candidiasis can occur, although this is uncommon. Allergic bronchopulmonary candidiasis should be considered in patients with ABPA with serologic and skin tests negative for *Aspergillus*. In addition, cases of chronic eosinophilic

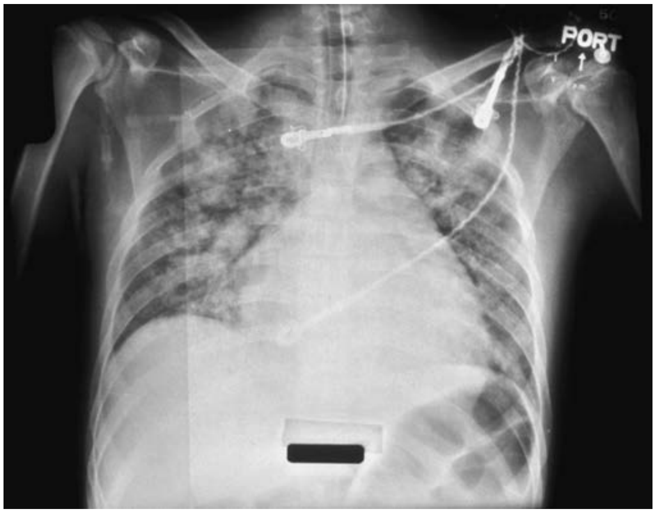

Figure 132-9 The radiographic features of *Candida* pneumonia in a patient with acute leukemia and severe neutropenia in whom disseminated candidiasis developed. Diffuse bilateral infiltrates along with the characteristic macronodular lesions are shown. *(Reproduced with permission from Dr. G.P. Bodey.)*

pneumonia with peripheral eosinophilia and selective sensitization to *C. albicans* occur rarely in the absence of asthma. Early diagnosis and corticosteroid-based therapy may prevent late fibrosis in those patients. Finally, fatal aspiration pneumonitis characterized by intense inflammatory response and lack of deep-tissue invasion has been described in alcoholic patients.

■ Diagnosis

Diagnosis of pulmonary candidiasis is challenging and depends on evidence of tissue invasion.[16–20] Isolation of yeast from sputum does not prove invasive yeast infection of the respiratory tract because of contamination by commensals from the oropharynx. *Candida* is present in the oropharynx of approximately 20% to 40% of all patients, especially those with chronic lung disease and those receiving prolonged antibacterial treatment.[15,16]

Bronchial washings and BAL specimens provide a more representative picture of the respiratory pathology compared to sputum. However, they can still be contaminated with mouth flora. At least in a selected group of patients with acute leukemia and severe neutropenia, if no other organisms are present and abundant *Candida* yeast cells and pseudohyphae are detected in the cytologic examination of BAL specimens, clinical suspicion of *Candida* pneumonia should be high.[15,16] On the other hand, cultures from lung specimens negative for *Candida* spp. have a high negative predictive value and virtually exclude *Candida* pneumonia.[15–18]

Histopathologic demonstration of tissue invasion by *Candida* spp. in open lung biopsy or CT-guided fine-needle aspiration of peripheral nodular lesions is definitive, although such biopsies are difficult to perform in pancytopenic patients with pneumonia and are prone to sampling error. Transbronchial biopsy revealing tissue invasion by *Candida* spp. is also diagnostic.

Isolation of *Candida* from the blood may be helpful in the diagnosis of disseminated candidiasis; however, the organism may not be isolated even from multiple blood culture specimens in up to 40% of patients with widespread infection demonstrated at autopsy.[15–21] The use of lysis centrifugation, the BacT-Alert system that monitors CO_2 production, and the high-volume BACTEC system with infrared detection has improved the yield of *Candida*-positive blood cultures. A variety of methodologies have been developed to detect circulating *Candida* antigens, nucleic acids, and metabolites. Among these non-culture-based diagnostic methods, PCR and β-D-glucan assays in serum hold most promise for adoption in routine clinical microbiology practice.[15] Of interest, in a recent prospective study of invasive candidiasis both PCR and serum β-D-glucan assays had higher sensitivity than blood cultures among patients with deep-seated candidiasis (88% and 62% vs. 17%, respectively); the combination of both the PCR and β-D-glucan assays resulted in 98% sensitivity. In addition, β-D-glucan levels seem to be a prognostic marker for treatment response in invasive candidiasis. The T2 *Candida* molecular diagnostic panel uses T2 magnetic resonance to detect *Candida* DNA directly within whole blood samples and shows improved sensitivity over blood cultures and other molecular detections methods especially in the setting of antifungal therapy. However, it is associated with high cost and the need for specialized equipment.[15]

In cases of disseminated candidiasis, characteristic eye lesions suggestive of *Candida* infection may develop;[15] hence, a careful ophthalmologic examination should be performed when this infection is suspected. In addition, typical maculopapular or nodular skin lesions have been described in up to 10% of patients with hematogenous candidiasis.[15] Some of these patients also have associated myositis, particularly in cases of *C. tropicalis* infection. *Candida* spp. can be identified in the dermis and cultured from about half of all biopsy samples. Finally, CT scans of the abdomen may suggest hepatosplenic candidiasis in compromised hosts with an unrevealing microbiologic evaluation.

■ Treatment

Primary *Candida* pneumonia is considered a life-threatening infection, with mortality rates approaching 70% in severely immunocompromised patients.[16–20] Therefore, rapid clinical diagnosis and prompt initiation of systemic antifungal therapy are important upon suspicion of the infection in the appropriate setting.

Given the rarity of primary *Candida* pneumonia, there are no controlled studies of its treatment. Historically, most patients with primary *Candida* pneumonia have received AMB-D (0.7–1.0 mg/kg/d) for a minimum of 2 weeks after all signs and symptoms of infection disappeared and until bone marrow recovery in those with neutropenia.[15] In cases of secondary *Candida* pneumonia associated with hematogenously disseminated infection, therapy directed at disseminated candidiasis rather than at *Candida* pneumonia is indicated.[15] Over the past two decades, several antifungal agents, including fluconazole and the newer triazoles (especially voriconazole), lipid formulations of AMB, and the echinocandins, have become available for the treatment of invasive candidiasis, showing comparable efficacy and significantly less toxicity when compared with AMB-D in several prospective randomized trials.[15]

Echinocandins are the preferred antifungal agents in the treatment of invasive candidiasis.[15] All three available echinocandins, including caspofungin, micafungin, and anidulafungin, have shown comparable, broad-spectrum fungicidal activity against *Candida* spp., including azole-resistant non-*albicans Candida* spp.[15] In fact, because of their potency, minimal toxicity, and superior activity when compared to AMB-D and fluconazole in randomized controlled studies in patients with candidemia, the echinocandins have become the drug of choice for candidemia/candidiasis in seriously ill and unstable patients.

The accumulating experience with the treatment of other invasive pulmonary mycoses with echinocandins holds promise for the use of these agents in the treatment of *Candida* pneumonia. However, because of the rarity of *Candida* pneumonia a definite treatment of choice for this entity has not been endorsed in recently published guidelines on treatment of *Candida* infections.[15] Thus, with all of the limitations of the aforementioned studies, and given the fact that fluconazole has been used extensively for prophylaxis in many institutions, initiation of therapy for *Candida* pneumonia with an echinocandin with subsequent switch to an azole may be a reasonable approach in such cases.[15] Also, using higher doses of fluconazole (800 mg/d), at least initially, may be appropriate in nonneutropenic patients.

PULMONARY MUCORMYCOSIS (FORMERLY ZYGOMYCOSIS)

Mucormycosis (formerly zygomycosis) has recently emerged as an important opportunistic mycosis in severely immunocompromised patients with hematologic malignancies and recipients of stem cell or organ transplantation.[25–27] Zygomycosis, the previous terminology for infections caused by fungi of the order Mucorales, is no longer appropriate due to a taxonomic reclassification that abolished Zygomycetes as a class. Necrotizing pneumonia is a predominant feature of mucormycosis, especially in severely immunocompromised patients.[25,27]

Fungi of the order Mucorales are distributed in six families, each of which can cause serious invasive infections (Table 132-7). Species of the family Mucoraceae are isolated more frequently from patients with mucormycosis than are species of any other family.[25,27] Among the Mucoraceae, *Rhizopus oryzae* (*Rhizopus arrhizus*) causes the vast majority (>70%) of Mucorales infections. Other less frequently encountered species of the Mucoraceae family include *Rhizopus microsporus*, *Lichtheimia* (formerly known as *Absidia* species), *Apophysomyces elegans*, *Mucor* species, and *Rhizomucor pusillus*. *Cunninghamella bertholletiae* is an increasingly reported cause of mucormycosis and appears to be the most virulent Zygomycetes species in humans.[25] All of these organisms are indistinguishable by histopathology. Various terms have been used in the past to indicate infections caused by Mucorales, such as mucormycosis, phycomycosis, and simply mucor. However, the more accurate term *mucormycosis* is used throughout this chapter to indicate opportunistic mold infections in humans caused by Mucorales, because this is the taxonomically correct description.

TABLE 132-7 Classification of Fungi in the Class Zygomycetes, Order Mucorales[a]

1. MUCORACEAE

[b] *These species are the more common etiologic agents associated with mucormycosis in humans.*

Disease Manifestations/Epidemiology/Risk Factors

The Mucorales are saprophytic fungi ubiquitous in soil and decaying organic material. Mucorales species that are pathogenic in humans grow rapidly on any carbohydrate substrate and produce abundant sporangiospores via asexual reproduction.[24] Mucorales are also capable of sexual reproduction via fusion of two hyphae and formation of thick-walled structure called zygosporangium under stress conditions. Although sexual reproduction has been linked to virulence of *Mucor circinelloides* in preclinical studies, its significance during human invasive infections remains uncharacterized. Spores produced by the fungi become airborne, and inhalation of Mucorales conidia into the respiratory tract occurs daily. Even though these fungi grow in many ecological niches, the rarity of mucormycosis reflects the low virulence potential of Mucorales in immunocompetent hosts. For unclear reasons, the incidence of Mucorales infections, particularly of *Cunninghamella*, *Absidia*, and *Apophysomyces* spp., is higher in male patients (65%) than in female patients. The most common forms of mucormycosis based on anatomic localization include (a) rhinocerebral infection (39%), (b) pneumonia (24%), (c) disseminated infection (23%), (d) cutaneous/soft tissue infection (19%), (e) gastrointestinal infection (7%), and (f) uncommon presentations (7%). When compared to other opportunistic molds, Mucorales tend to infect a broad, more heterogeneous population of human hosts, including immunocompetent individuals. Specifically, Mucorales cause acute angioinvasive infections in patients with a variety of debilitating and immunosuppressive conditions, including those with poorly controlled diabetes mellitus (especially with diabetic ketoacidosis), neutropenia, malignancies, burns, or chronic renal failure with iron overload, as well as recipients of transplants and patients with renal failure receiving the iron (and aluminum)-chelating agent deferoxamine.[24] A common denominator of the aforementioned predisposing conditions is the loss of intra- and extracellular immune effector mechanisms, including nutritional immunity, which physiologically restrict fungal growth. Professional phagocytes mediate protective immunity against all filamentous fungi. However, there are important differences in the cellular and molecular host defense mechanisms against Mucorales as compared to *Aspergillus*, which are relevant to the unique pathogenesis of mucormycosis. It is important to emphasize that dissemination may occur from any of the primary sites of

Mucorales infection, mainly in patients with profound immunosuppression.

Of note, particular host immune defects predispose to different forms of mucormycosis. For example, patients with diabetic ketoacidosis are prone to the development of the rhinocerebral form of mucormycosis but less often suffer from pulmonary or disseminated infection. In contrast, pulmonary mucormycosis typically affects severely immunocompromised individuals, including patients with high-risk hematologic malignancies and recipients of hematopoietic stem cell and organ transplants. The predominance of pulmonary infection in those patients may be a result of chemotherapy-related defects in innate pulmonary host defenses associated with neutropenia and/or chemotherapy-induced mucociliary dysfunction. Prolonged and severe neutropenia is the sole identifying risk factor in approximately 15% of all reported mucormycosis cases. Nonetheless, like aspergillosis, mucormycosis is increasingly reported as a late (1–6 months), or very late (>6 months) community-acquired infection in nonneutropenic, HSCT recipients post-engraftment, especially in the setting of multiple, overlapping, and cumulative mechanisms of immunosuppression during GvHD treatment. In these patients, severe immunodeficiency due to high-dose glucocorticosteroid therapy and/or other immunosuppressive therapies frequently coexists with other comorbidities that are interrelated and difficult to quantify, such as hyperglycemia, metabolic acidosis, renal failure, iron overload, malnutrition, advanced age, and CMV infection.

A significant increase in the rates of mucormycosis has been observed recently among severely immunocompromised individuals classically at risk for other opportunistic mold infections, such as patients with acute leukemia and transplant recipients.[24–26] An autopsy study in hematologic malignancy patients from a single cancer institution with high background rates of mucormycosis reported a significant threefold increase in prevalence of autopsy-proven mucormycosis cases from 0.9% to 3% during the study period (1989–2003). Importantly, most of these infections were diagnosed postmortem. Similarly, there was a fourfold increase in the overall incidence of mucormycosis during a period of active surveillance at 25 U.S. transplant centers from 2001 to 2006, whereas the incidence of other opportunistic molds remained constant. In the aforementioned study the overall cumulative annual incidence (CI) of mucormycosis was the highest (0.29%) in HSCT recipients, particularly those receiving transplant from an HLA-unrelated donor (0.85%). Among solid-organ transplant recipients, the overall 12-month CI of mucormycosis was 0.07%, with lung transplants and liver transplants having the highest incidence of mucormycosis, at 0.18% and 0.16%, respectively. Of note, there was a seasonal variation in incidence of mucormycosis with declining rates among the groups transplanted in the first 4 months of each year. National studies in Europe that used administrative data from hospital records to capture cases of mucormycosis also demonstrated a significant increase in incidence of mucormycosis within a 10-year period.[24–26]

Of concern, a growing proportion of pulmonary mucormycosis cases manifest as breakthrough infections in patients receiving antifungal agents with activity against aspergillosis but not mucormycosis (i.e., voriconazole, echinocandins). Case series in high-risk leukemia and allogeneic HSCT patients suggest that mucormycosis should be considered whenever fungal sinusitis develops while on *Aspergillus*-active antifungal prophylaxis (i.e., voriconazole), especially in patients with prolonged immunosuppression, underlying diabetes or malnutrition, and in the setting of negative *Aspergillus* galactomannan assay and "therapeutic" voriconazole serum levels (e.g., voriconazole levels >2 ng/mL). Animal studies have demonstrated increased virulence of *Mucorales* spp. following voriconazole pre-exposure; previous voriconazole use has been independently associated with the development of mucormycosis in leukemia and transplant patients. Other studies have reported an increase in mucormycosis cases prior to the introduction of voriconazole, and a recent randomized trial on voriconazole prophylaxis in low- to moderate-risk allogenic HSCT recipients with favorable prognostic features did not find a higher incidence of mucormycosis. Hence, additional factors including underlying host immunoparalysis, evolving transplant practices, and immunosuppressive strategies that ultimately result in improved posttransplant survival could potentiate the association of voriconazole with development of mucormycosis. Very late-onset mucormycosis, occurring 2 years or more after transplantation, has been reported in a significant proportion of HSCT (13.8%) and SOT (33.3%) recipients in a multicenter prospective surveillance study.

There are inherent problems with epidemiologic studies on mucormycosis related to challenges in establishing a diagnosis and capturing shifts in prevalence of classic or unknown risk factors of infection in high-risk populations. Furthermore, surveillance strategies to capture the true incidence of mucormycosis are imperfect given that the diagnosis is difficult to achieve antemortem. Instead of registries that create databases based on hospital coding diagnoses, development of active surveillance programs is needed with long-term follow-up in selected high-risk patient groups such as transplant recipients.

■ Mycology

Mucorales are molds characterized by growth of hyphae in the environment and in tissue. They grow rapidly—within 2 to 5 days on most culture media—as fluffy gray or brownish colonies, with many of the species demonstrating aggressive vertical growth toward the lid of the Petri dish; these species are referred to as "lid lifters."[24] As the *Mucorales* colony matures, the mycelium may darken and exhibit a black pepper–like effect as large numbers of sporangia are formed. Cycloheximide inhibits the growth of these fungi, and media that contain this compound, such as Mycosel and mycobiotic agar, should not be used. Clinical tissue samples potentially infected with the *Mucorales* should be chopped, not ground, for inoculation into microbiologic cultures. All pathologic species grow well at 37°C.[24]

Microscopic examination for the presence and location of rhizoids and apophyses and to determine the morphology of the columellae differentiates the genera. Isolating and speciating the organism is important for selection of treatment. However, morphologic identification of Mucorales species is often imprecise.

■ Immunopathogenesis

Quantitative (i.e., neutropenia) or qualitative (i.e., associated with glucocorticoids, hyperglycemia, and/or acidosis) defects in phagocytic cell activity permit unrestricted growth of the hyphal form and development of mucormycosis. In particular, both hyperglycemia and acidosis are known to impair chemotaxis and the killing activity of phagocytic cells against Mucorales by impairing oxidative and nonoxidative mechanisms.[24] Likewise, corticosteroids impair migration, ingestion, and phagolysosome fusion in human macrophages.[3] However, the molecular mechanisms that account for attenuated phagocytic function in patients with hyperglycemia, ketoacidosis, or steroids are only partially characterized.

Iron metabolism has a central role in pathogenesis of mucormycosis.[3,25] Thus, patients with iron overload states, including those undergoing chelation therapy with deferoxamine, are uniquely predisposed to mucormycosis. Deferoxamine abolishes the fungistatic effect of serum and increases in vitro fungal growth by acting as a siderophore for Mucorales species.[25] The key role of iron utilization in pathogenesis of mucormycosis is further illustrated by the fact that conditional inactivation of the *R. oryzae* high-affinity iron permease gene, FTR1, renders the fungus nonpathogenic in mice.[25] Similarly, the increased susceptibility to mucormycosis of patients with acidosis, including diabetic acidosis, is attributed to increased availability of serum iron partially due to diminished affinity of transferrin for free iron at a lower pH (<7.4). Unlike deferoxamine, the other iron chelators, such as deferiprone and deferasirox that lack xenosiderophore activity for *Rhizopus*, induce an iron-starvation effect to the fungus and have shown to be protective in animal models of mucormycosis and in anecdotal reports of human infection.

A hallmark of mucormycosis is extensive angioinvasion with resultant vessel thrombosis and tissue necrosis (Fig. 132-10). Apart from mucoricin toxin production, interaction of Mucorales spores with endothelial cells appears to play a critical role in angioinvasion. Ibrahim et al. identified glucose-regulated protein 78 (GRP78) as a novel host receptor that selectively and specifically interacts with *Rhizopus* mediating invasion and damage of human endothelial cells by the fungus.[25] Of interest, elevated glucose and iron levels upregulate GRP78 expression and promote endothelial cell invasion and damage by *R. oryzae* in a receptor-dependent manner. From the fungal perspective, Mucorales bind to GRP78 endothelial receptors via a specific class of spore surface proteins, CotH invasins, which are unique for this class of fungi. Treatment of mice with anti-CotH antibodies augments opsonophagocytic uptake of fungal conidia by neutrophils and protect mice from development of invasive disease.

■ Clinical Manifestations

Although concomitant sinus infection is suggestive of pulmonary mucormycosis, the clinical manifestations of pulmonary infection are almost indistinguishable from those caused by the more common opportunistic mold *Aspergillus*.[24,26] Therefore, timely diagnosis is critical in the outcome of this infection because first-line antifungal agents typically used for aspergillosis, such as voriconazole, lack activity against Mucorales.

Clinical symptoms of pulmonary mucormycosis are subtle and nonspecific even at late stages of infection, especially in neutropenic patients and those receiving immunosuppressive therapies that dampen immune responses. Pulmonary mucormycosis frequently manifests with persistent fever on broad-spectrum antibiotics, nonproductive cough, progressive dyspnea, and pleuritic chest pain.[26] Infection has a propensity to traverse tissue planes in the lung, including the bronchi, diaphragm, chest wall, and pleura. Hyphal invasion of blood vessels results in necrosis of the surrounding parenchyma, ultimately leading to cavitation or potentially fatal hemoptysis. In patients with hematologic malignancies, clues for distinguishing pulmonary mucormycosis from IPA may include the presence of necrotic lesions in palate, severe sinusitis, rhino-orbital extension, prophylaxis with antifungals that possess activity against aspergillosis but not mucormycosis (i.e., voriconazole and the echinocandins), and possibly the repeated absence of detectable *Aspergillus* galactomannan antigen and/or b-glucan in the serum.[24,26] Unfortunately, the frequent coexistence of bacterial or mixed fungal pneumonia (up to 22% in a single-institution observational study) in high-risk hematologic malignancy patients can further complicate early diagnosis and management of pulmonary mucormycosis. Pulmonary mucormycosis rapidly spreads to the contralateral lung and distal organs if not promptly treated. While patients with pulmonary mucormycosis usually die from disseminated disease before respiratory failure occurs, dissemination is rarely detected antemortem. The overall mortality rate of pulmonary mucormycosis ranges from 50% to 70% but exceeds 90% with extrathoracic dissemination.[24,26]

A multitude of patterns may be present in a regular chest radiograph of patients with pulmonary mucormycosis, including lobar consolidation, nonspecific infiltrates, cavities, masses, and nodules. Similar to IPA, high-resolution chest CT is the best method of determining the extent of pulmonary mucormycosis and typically demonstrates evidence of the infection earlier than standard chest radiographs. While nodular opacities without an air bronchogram indistinguishable from those of aspergillosis are the most common findings on CT scan, the presence of multiple nodules (≥10) and, to a lesser degree, pleural effusions may favor the diagnosis of pulmonary mucormycosis.[24] Halo and air crescent signs are encountered less frequently in leukemic patients with pulmonary mucormycosis compared to pulmonary aspergillosis. However, the presence of air crescent sign in centrally located lesions reflects an increased risk of pulmonary artery erosion and massive hemoptysis. Small case series suggested that a reverse-halo sign, a focal round area of ground-glass attenuation surrounded by a ring of consolidation, may be a common early radiographic finding in neutropenic patients with invasive pulmonary mucormycosis versus aspergillosis, especially when accompanied by a thick (>1 cm) outer consolidation rim.[24,26]

Atypical presentations of pulmonary mucormycosis include chronic infection with constitutional symptoms that last for several months in relatively immunocompetent hosts, multiple mycotic pulmonary artery aneurysms and pseudoaneurysms, bronchial obstruction, asymptomatic solitary nodules, or even normal chest radiographs. Of interest, patients with diabetes mellitus have an apparent predilection for the development of endobronchial lesions, accounting for more than 80% of reported cases in the literature. Furthermore, pulmonary mucormycosis tends to present with a less fulminant, subacute clinical course in these patients. However, endobronchial lesions may occasionally lead to obstruction of major airways or erosion of major pulmonary blood vessels and fatal hemoptysis. In lung transplant recipients, ulcerative tracheobronchitis at the bronchial anastomotic site is rarely caused by Mucorales when compared to *Aspergillus*; however, changes in immunosuppressive and antifungal prophylaxis practices could lead to the emergence of this infection in the future.[24]

Similar to *Aspergillus* spp., Mucorales species rarely produce an asymptomatic mycetoma within a pre-existing lung cavity. Allergic *Rhizomucor* sinusitis has been reported in immunocompetent individuals. In addition, hypersensitivity pneumonitis caused by *Rhizopus* has been described in farm workers as well as in Scandinavian sawmill workers (wood trimmer's disease).[24]

■ Diagnosis

Little improvement has been made over the past few decades in the diagnosis of mucormycosis, which still relies on histopathology and traditional culture methods. Timely diagnosis of mucormycosis requires a high index of suspicion and largely depends on histopathological demonstration of tissue invasion by the characteristic hyphae or by isolation of Mucorales species in cultures of sterile tissue, which necessitates implementation of an invasive procedure. Tissue swabs, sputum, or bronchial alveolar lavage fluid cultures are usually nondiagnostic, but provide an important indication of disease and allow for the establishment of probable infection in immunocompromised patients.[24] Blood cultures rarely, if ever, grow Mucorales species despite the angioinvasive nature of these pathogens.

Mucorales stain poorly with PAS and Gram stains but stain very well with Grocott–Gomori methenamine-silver. Treatment with fluorescent stains such as calcofluor-white or Blankofluor may aid in detection of hyphal elements and improve the discrimination between septated and aseptate molds. In tissue specimens Mucorales appear as broad (10–20 μm in diameter) nonseptate hyphae with branches occurring at right angles (Fig. 132-11). Differentiation of *Aspergillus*, *Fusarium*, *Scedosporium* spp., or other hyalohyphomycetes from Mucorales hyphae in tissue involves visualizing thinner, more regularly shaped fungal elements with more frequent acute angle branching and the presence of septae in the former group.[24]

In the majority of patients with pulmonary mucormycosis, establishment of a definite diagnosis with biopsy is hampered by the presence of comorbidities, such as thrombocytopenia. Furthermore, routine laboratory cultures, even if performed from tissue specimens with abundant Mucorales hyphal growth, have a yield of less than 50%. Recovery from tissue can be improved by mincing (not homogenizing) tissue and use of culture techniques that simulate in vivo growth, including incubation at 35° to 37°C in semianaerobic conditions.[24,26]

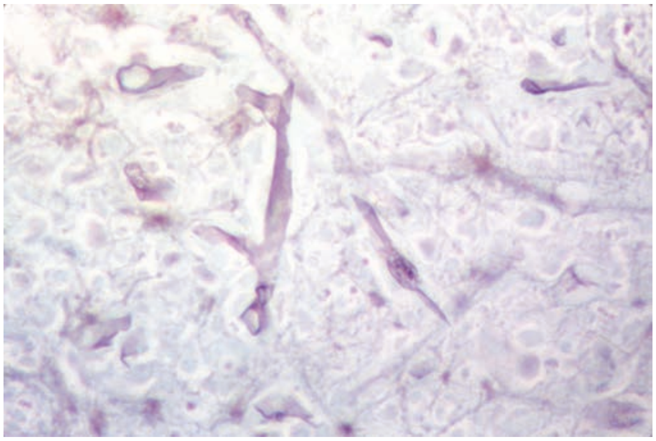

Figure 132-11 Histopathologic features of Zygomycetes hyphae in a profoundly neutropenic patient with leukemia in whom pulmonary mucormycosis developed. Of note is the characteristic broad nonseptate or rarely septate hyphae with branches at right angles. H&E stain, ×400. *(Reproduced with permission from Dr. G.P. Bodey.)*

The importance of early differentiation of pulmonary mucormycosis from other IMIs has generated considerable interest in the development of surrogate diagnostic tests such as detection of specific antigens or nucleic acid by PCR. Unfortunately, serology-based diagnostic assays such as *Aspergillus* galactomannan and b-glucan are not useful for detection of mucormycosis. Other molecular diagnostic techniques using PCR assays in serum samples or paraffin wax embedded tissue or in situ hybridization techniques are promising but remain investigational. In a prospective study of CT-guided percutaneous lung biopsy samples from high-risk patients with suspected fungal pneumonia, investigators demonstrated that early diagnosis and differentiation of pulmonary mucormycosis from IPA could be improved using a three-step analysis approach of biopsy specimens of lung lesions that included calcofluor-white staining to rapidly distinguish septated versus aseptate hyphae, *Aspergillus* galactomannan and PCR testing for rapid identification, and PCR testing of DNA in selected biopsy specimens where aseptate hyphae were observed or *Aspergillus* markers were negative.[24] These promising results require validation in a wider range of patients before PCR becomes a standardized adjunctive diagnostic test for mucormycosis.

■ Treatment

Successful treatment of pulmonary mucormycosis relies on timely diagnosis, reversal of underlying predisposing factors, early and broad surgical debridement of infected tissue (when possible), and rapid administration of effective antifungal therapy in the context of a multidisciplinary approach.[24,26] Cooperation among the primary care physicians, infectious disease consultants, surgeons, microbiologists, and pathologists is essential in the early stages of infection to avoid unnecessary diagnostic and treatment delays that increase patient morbidity and mortality.[26] For example, patient outcomes can be improved if initial treatment decisions are based on frozen tissues biopsy rather than from paraffin-embedded tissue samples. Similarly, delays in the administration of effective systemic antifungal therapy within the first few days of diagnosis increase the probability of patient death due to progressive and/or disseminated infection. In addition, rapid correction of underlying conditions such hyperglycemia, diabetic ketoacidosis or other form of acidosis, tapering of corticosteroids, and other immunosuppressive drugs is critical to outcome. Notably, there have been rare cases of pulmonary mucormycosis with spontaneous regression of infection after correction of diabetic ketoacidosis.[24]

Antifungal Treatment

With the exception of the recently completed DEFEAT *Mucor* study, there are no other prospective studies for the treatment of pulmonary mucormycosis because of the rarity and heterogeneity of the infection. Most evidence on the activity of existing antifungal agents comes from small case series, anecdotal case reports, and animal studies. Based on consensus guidelines,[24] the liposomal formulations of AMB have become the mainstay for treating mucormycosis in view of their favorable toxicity profile and comparable clinical outcomes with those historically reported for conventional AMB-based therapy. Thus, in the largest reported case series of mucormycosis including 24 patients who received a lipid complex of AMB for refractory disease or intolerance of conventional AMB, the overall response rate was 71%, without significant toxic effects even in patients with pre-existing renal disease. Animal models of pulmonary mucormycosis suggest a possible benefit for early administration of higher dosages of lipid AMB, and a phase 2 clinical study of 10 mg/kg/d liposomal AMB in mucormycosis will further address this question (*clinicaltrials.gov/ct2/show/NCT00467883*).[24,25] Recent guidance from European Confederation for Medical Mycology recommends 5 to 10 mg/kg/d liposomal AMB with a dose of 10 mg/kg/d in cases of CNS involvement.[24,25]

Alternative routes of administration of amphotericin B as an adjunct to systemic therapy have been reported in pulmonary mucormycosis, although the efficacy of this approach is difficult to discern. For example, case reports describe the successful treatment of cancer patients with pulmonary mucormycosis using systemic therapy and ABLC aerosolized with a Respirgard II nebulizer, and direct instillation of amphotericin B within pulmonary cavities or into the pleural space.

In a recent, open-label, single-arm study the efficacy of the newer triazole isavuconazole as first-line treatment was tested and found to be similar to that of a historic matched control group treated with amphotericin B formulations. This limited size study enrolled 21 patients and compared them with 33 matched patients from the FungiScope registry. As a result, isavuconazole has FDA approval for first-line treatment of mucormycosis and has been endorsed in recent guidelines. Importantly, cases of breakthrough mucormycosis in patients receiving isavuconazole secondary prophylaxis have been reported, and the activity of this antifungal is variable across different Mucorales species.[24]

Posaconazole, an orally available broad-spectrum triazole, possess reliable activity against Mucorales and was until recently the only alternative therapy for mucormycosis. In an open-label salvage trial, the overall success rate of posaconazole was 70% in 24 patients and was associated with minimal toxicity. Similarly, a retrospective review of posaconazole-based salvage therapy in 91 patients who had refractory mucormycosis indicated an overall success rate of 61%, including a success rate of 65% in the group of patients with pulmonary mucormycosis.[24] Nonetheless, posaconazole exerts limited activity against *Rhizopus* spp. in neutropenic mouse models, and cases of breakthrough mucormycosis in HSCT recipients while on posaconazole prophylaxis have been reported. Treatment with oral posaconazole has important pharmacokinetic limitations related to drug interactions and the poor absorption of the drug, especially in patients with mucositis and those with poor dietary intake, while steady-state plasma concentrations of posaconazole are not reached until around 1 week of therapy.[26] Drug interactions can be problematic, especially in patients receiving drugs that accelerate CYP P450 metabolism (i.e., rifampicin), or acid suppression therapy particularly with proton pump inhibitors. Therefore, it is preferable that patients with mucormycosis should initially receive several days of a lipid AMB formulation before being started on posaconazole therapy, and plasma drug level monitoring may be necessary in selected patients. Patients with persistently low or undetectable serum drug levels, poor oral intake, or GI dysfunction (severe nausea, diarrhea) often must be transitioned back to intravenous liposomal AMB even in the absence of obvious disease if they are receiving additional immunosuppressive therapy. Overall, posaconazole seems to be a favorable option for less severely immunocompromised patients who need to be on continuous long-term antifungal therapy given the high risk for relapse of mucormycosis. The new (IV and oral slow-release tablet) formulations of posaconazole display improved pharmacokinetics and have been recommended as an alternative first-line therapy for mucormycosis.

Echinocandins lack activity against Mucorales in vitro, and clinical experience with caspofungin in the treatment of mucormycosis is extremely limited. Nevertheless, in case reports and a study with a model of disseminated mucormycosis in diabetic mice, echinocandins appear to have some role, especially in combination with a polyene, in serious cases of mucormycosis.[24] A combination ABLC-caspofungin treatment regimen was associated with improved therapeutic success (100% vs. 45%; $p = 0.02$) in 41 diabetic patients with biopsy-proven, mostly rhino-orbital cerebral mucormycosis.[26] Recent ECMM recommendations are against the use of echinocandins in management of mucormycosis.[24]

The duration of treatment required for mucormycosis should be highly individualized. Near normalization of radiographic imaging, negative biopsy specimens, and cultures from the affected site, and recovery from immunosuppression, are indicators that a patient is a candidate for stopping antifungal therapy. Intracellular persistence of dormant Mucorales conidia inside tissue macrophages supports the use of long-term secondary prophylaxis in patients with mucormycosis.

Surgical Treatment

Because mucormycosis is a highly angioinvasive infection with resulting extensive thrombosis and tissue necrosis, antifungal agents often display poor penetration at the site of infection. Therefore, even if the causative *Mucorales* strain is susceptible to the antifungal agent in vitro, the agent may be ineffective in vivo. Surgical debridement of infected lung tissue should be performed on an urgent basis. In patients with pulmonary mucormycosis, surgical treatment in conjunction with antifungal therapy has been shown to significantly improve survival when compared with antifungal therapy alone. Hence, a comprehensive review of cases of pulmonary mucormycosis showed that the mortality in patients who received antifungal agents alone was 55% versus 27% in patients who received antifungal agents and surgery.[24] Removal of as much of the infected or devitalized tissue as possible while the infection is localized has the greatest benefit. Lobectomy is often required, and pneumonectomy may be necessary for proximal or extensive involvement. Also, repeated procedures may be needed. The benefit of pulmonary resection diminishes as dissemination occurs.

Other Adjunctive Therapies

Small case series implicate that treatment with hyperbaric oxygen (HBO) may be a beneficial adjunct to standard therapy for mucormycosis, particularly in patients with diabetes mellitus who have rhinocerebral disease.[24] HBO has pleiotropic properties by promoting wound healing, phagocytic cell function, and oxidative killing mechanisms of Mucorales by AMB and also displays direct antifungal activity. However, data on treatment with HBO of pulmonary mucormycosis are scarce, and a role in this setting remains uncertain.

The role of adjunctive cytokine therapy for mucormycosis has not been extensively studied. Cytokines that activate phagocytic activity, such as IFN-γ and GM-CSF, increase the killing efficacy of phagocytic cells against Mucorales species in vitro. Case reports indicate a favorable outcome in selected patients with rhinocerebral mucormycosis who received IFN-γ and GM-CSF adjunct salvage treatment. In selected neutropenic patients, granulocyte transfusion may be a useful bridge until neutrophil recovery, although the clinical benefit remains unproven and serious adverse effects that resemble immune reconstitution inflammatory syndrome (IRIS), including pulmonary toxicity and accelerated cavitation/bleeding, have been reported in patients with opportunistic lung mycoses.[24,26] Importantly, granulocyte transfusions contain not only neutrophils but also substantial number of lymphocytes, and HLA alloimmunization can be a major complication of granulocyte transfusions. Thus, the benefits and risks of granulocyte transfusions should be carefully assessed on an individual basis, particularly for patients who are candidates for HSCT. Adoptive T cell–based immunotherapeutic strategies are feasible and could represent an attractive future strategy in the management of mucormycosis.

The central role of iron metabolism in the pathogenesis of mucormycosis supports the hypothesis of using iron chelators without xenosiderophore activity, such as deferiprone and deferasirox, as adjunctive antifungal therapy.[26] In contrast with deferoxamine, such iron chelators induce iron starvation in the fungus, thereby inhibiting growth in vitro in the presence of iron and improving survival in a diabetic ketoacidosis animal model of mucormycosis. Case reports imply that deferasirox with antifungals may be less effective in neutropenic patients than in diabetic ketoacidosis patients. Moreover, the bioavailability of oral deferasirox in immunocompromised patients with mucositis due to chemotherapy or GvHD of the gut is unknown. Importantly, a recently completed, phase 2, double-blind, randomized, placebo-controlled trial of adjunctive deferasirox therapy failed to demonstrate a benefit of the combination regimen in 20 patients with mucormycosis (DEFEAT *Mucor* trial, NCT00419770).

EMERGING OPPORTUNISTIC PULMONARY MYCOSES

Over the past three decades, and with the ever-expanding spectrum of immunocompromised patients, we have witnessed the emergence of less common but medically important opportunistic fungal pathogens, including septate filamentous fungi such as hyalohyphomycetes (e.g., *Fusarium*, *Scedosporium*, *Lomentospora prolificans*, *Trichoderma* species), dematiaceous fungi (e.g., *Phaeohyphomycetes*), endemic dimorphic pathogens (e.g., *Penicillium marneffei*), and rare pathogenic yeasts (e.g., *Trichosporon* species).[27–30] The diagnosis of invasive fungal pneumonia caused by these uncommon filamentous fungi is challenging because of the similarity of the manifestations and histopathologic features of these mycoses with those of IA. Given the fact that most of these infections have a poor outcome because of broad-spectrum resistance to conventional antifungal agents and the severity of underlying immunodeficiency, timely diagnosis is critical for outcome. Therefore, pulmonary infections caused by hyalohyphomycetes, including *Fusarium* and *Scedosporium* and *Lomentospora prolificans* species, are discussed below.

■ Pulmonary Fusariosis

Fusarium spp. are ubiquitous filamentous fungi found in soil, water, and decaying material. Although *Fusarium* is a well-known plant pathogen, only a few of the 50 different species have been reported to be pathogenic in humans, including *Fusarium solani*, *F. oxysporum*, *F. moniliforme*, *F. verticillioides*, *F. dimerum*, and *F. proliferatum*.[27] Of these species, *F. solani* is the most virulent, causing half of all cases of invasive fusariosis reported in humans. Since the description of the first case of disseminated fusariosis in a child with acute leukemia in 1973, invasive fusariosis has emerged in some tertiary care oncology centers as an important IMI in profoundly immunocompromised patients with hematological malignancy.[29]

There seems to be a distinct seasonal peak and geographic distribution of invasive fusariosis. The vast majority of cases have been reported in the United States during the rainy summer season, when the dispersion of fusarial conidia in the air is most pronounced.[29] More than 90% of human invasive fusariosis cases occur in neutropenic patients with hematologic malignancies, especially those with acute leukemia. Another risk factor for invasive fusariosis is GvHD treated with high doses of corticosteroids during the postengraftment period in HSCT recipients.[27–31]

The skin and respiratory tract are the primary portals of entry for *Fusarium* infection. In particular, onychomycosis and paronychia are typical skin entry sites in the immunocompromised host. Inhalation of *Fusarium* conidia through the lung and paranasal sinuses by a severely immunocompromised host may lead to sinopulmonary infection characterized by angioinvasion, extensive tissue necrosis, and secondary dissemination. In addition, disruption of skin integrity because of local trauma or placement of a central venous catheter or in the setting of onychomycosis with associated cellulitis appears to be a relatively common portal of entry for disseminated *Fusarium* infection that involves the lung in immunocompromised hosts. The ability of *Fusarium* spp. to undergo adventitious sporulation with formation of microconidia in vivo facilitates dissemination and may account for the high rates of positive blood cultures and associated skin lesions in cases of fusariosis.[29] Neutrophils probably play the most critical role in the control of human *Fusarium* infections. Several studies have demonstrated that the prognosis for patients with fusariosis is associated with the prompt recovery of neutrophil counts. In fact, the mortality rate in patients with fusariosis in the setting of profound, prolonged neutropenia is essentially 100%, even with prompt administration of effective antifungal treatment, compared with a rate of approximately 30% in the setting of neutrophil recovery.[28]

Fusariosis in immunocompromised patients manifests in four major patterns: refractory fever of unknown origin, sinopulmonary infection or pneumonia, disseminated infection, and a variety of focal single-organ infections.[29] Sinopulmonary fusariosis and pneumonia occurs in more than 80% of patients and is most often clinically and radiographically indistinguishable from the much more common IA and other IMIs. Sinus involvement is also frequent, as it has been observed in up to 80% of cases in some reports.[29] One of the diagnostic challenges in immunocompromised patients with fungal pneumonia is differentiating between IA, invasive fusariosis, and mucormycosis. Hence, recovery of *Fusarium* spp. from cultures of blood (~70% fungemia) and other appropriate specimens and detection of GM antigen in serum (present in >80% of patients) is essential for a definite diagnosis.

The histopathologic picture of *Fusarium* is identical to that of *Aspergillus* and other hyalohyphomycetes (e.g., *Scedosporium* spp.) and may lead to misidentification. Even so, there are subtle differences in the histopathologic features of *Aspergillus* and *Fusarium* spp. that can facilitate differentiation between the two species based on the histopathology itself, including the presence of *Fusarium* chlamydosporia in tissue (Table 132-8).

Because hyalohyphomycetes (*Aspergillus* vs. *Fusarium* vs. *Scedosporium* spp.) have different levels of susceptibility to antifungal agents, the ability to differentiate between these molds in histopathology-positive but culture-negative cases using molecular identification methods could have significant implications on therapeutic decision-making. In situ hybridization directed against ribosomal 18 S RNA sequences was shown to rapidly and accurately distinguish *Fusarium*, *Aspergillus*, and *Scedosporium* spp. from histopathologic specimens.[28] However, further standardization of these promising molecular methods is needed. Proteomic-based approaches with the use of mass spectroscopy (MALDI-ITOF) are capable to provide rapid diagnosis of clinical isolates of *Fusarium*. These techniques are promising in diagnosis of fungal pathogens but require further standardization and are not widely available. Thus, tissue cultures remain the gold standard for differentiation between these fungi.

Despite the clinical similarities between pulmonary fusariosis and IPA, there are some characteristics that favor the diagnosis of invasive fusariosis (Table 132-8). First, *Fusarium* spp. are usually recovered from blood specimens in the setting of disseminated disease. The reported rate of positive blood cultures in patients with disseminated fusariosis ranges from 50% to 70%, and fungemia may be the only manifestation of the infection.[29] *Fusarium* is the most common mold associated with true fungemia in HSCT recipients.[31] This feature contrasts with disseminated IA and mucormycosis cases in which these molds are rarely (<5%) isolated from blood specimens, with the notable exception of *A. terreus*.

TABLE 132-8 Differentiating Features Among the Major Opportunistic Mold Infections of the Lung

Incidence	• *Aspergillus* causes the vast majority of cases of fungal pneumonia, followed by Mucorales
Predisposing factors	• Mucorales are associated with the presence of diabetes mellitus, acidosis, malnutrition, iron overload states, and voriconazole prophylaxis
Clinical features	• Skin lesions are more common in disseminated fusariosis (50%–70%) than in disseminated IA (<10%) and disseminated mucormycosis (<10%) • Skin lesions in fusariosis are different from those in IA and mucormycosis (*Aspergillus and* Mucorales skin lesions are fewer, less widespread, have a larger diameter, and present with a black eschar with a thinner erythematous halo) • Fungemia is more common in fusariosis (60%–70%) than in IA (<5%) and mucormycosis (virtually absent) • Fungemia also often occurs earlier in fusariosis than in IA (shortly before death or after death) • Mucorales *and Fusarium* spp. are highly resistant to antifungal agents and develop as breakthrough infections to antifungals with anti-*Aspergillus activity*
Histopathologic features	• Broad-based nonseptate or pauciseptate ribbon-like hyphae are pathognomonic for Mucorales • The presence of chlamydosporia in histopathology is pathognomonic for *Fusarium* spp.
CT features	• On CT scans, reverse halo sign, multiple (>10) nodules, and pleural effusions favor the diagnosis of pulmonary mucormycosis vs. IPA • Pulmonary mucormycosis has a predilection for the upper lung lobes
Serology	• Positive galactomannan antigen is virtually diagnostic for IPA; cross-reactivity of *Aspergillus* galactomannan antigen with *Fusarium* spp.

Another distinctive feature of invasive fusariosis is the high incidence (50%–70%) of necrotic skin lesions in patients with disseminated disease. This contrasts with the low incidence of skin lesions in patients with disseminated aspergillosis (<10%). In fact, skin lesions are frequently the sole diagnostic material for invasive fusariosis in a high-risk patient with presumed fungal pneumonia. Several patterns of skin lesions can be seen: subcutaneous nodules, purpura, red or gray macules and/or papules with or without progressive central necrosis, flaccid pustules, vesicles, and hemorrhagic bullae.[29] The most characteristic skin lesions encountered in cases of disseminated fusariosis are "ecthyma gangrenosum–like" lesions, which are red or gray macules with central ulceration or black eschar. *Fusarium* skin lesions are often tender, especially subcutaneous nodules, and can involve any skin site, although they appear predominantly in the extremities. Most patients have lesions at different stages of evolution. Accompanying myalgias are also common, reflecting concomitant muscle involvement.

Fusarium species are quite resistant to the arsenal of modern antifungal agents, and breakthrough infections to AMB or triazoles are common.[29] In particular, *F. solani* is the most resistant species within the genus. The mainstay in the treatment of fusariosis has traditionally been AMB-D. However, the in vitro susceptibility of *Fusarium* spp. to AMB-D is, at best, mediocre. Whether the in vitro susceptibility of *Fusarium* spp. alone can predict outcome is unclear because other factors, such as neutrophil recovery, are probably the most critical determinants of the prognosis for fusariosis. There have been reports of improved outcome of fusariosis with the use of high-dose lipid formulations of AMB. Hence, the mortality rate in patients who received high doses of a lipid complex of AMB (>5 mg/kg/d) was significantly lower (<30%) than that observed in patients who received conventional AMB-D doses (>75%) in a previous study.[29]

Among the antifungal triazoles, fluconazole and itraconazole are not active against *Fusarium* spp. However, the newer broad-spectrum triazoles voriconazole and posaconazole have variable in vitro activity against *Fusarium* spp. and may show promise in the management of fusariosis. A recent retrospective study evaluated the outcome of 73 patients with fusariosis treated with voriconazole either as frontline (22%) or salvage (78%) therapy, with an overall response rate of 47%. Another retrospective study in 21 patients with fusariosis refractory or intolerant to AMB-based therapy reported a 48% response rate in 10 patients receiving salvage posaconazole.[29] Given that AMB and the newer triazoles voriconazole and posaconazole are the most active agents against *Fusarium* spp., a strategy combining a lipid formulation of AMB with one of these triazoles is frequently employed in clinical practice. A retrospective study examined the rationale of combination therapy in 44 hematologic malignancy patients with fusariosis. The majority of these patients (73%) received combination therapy with amphotericin B and a triazole, with 41% response at 12 weeks after diagnosis. Overall, the rationale of combination therapy for fusariosis is reasonable and merits further investigation.[29] Isavuconazole displays less potent in vitro activity when compared to the other triazoles. Nonetheless, frontline isavuconazole therapy in a small case series of 7 patients (enrolled in VITAL and SECURE trials) resulted in 44% survival at 90 days.

Because the neutrophil count seems to be the most crucial prognostic determinant in fusariosis cases, a potentially beneficial adjuvant therapeutic strategy is to transfuse granulocytes obtained from G-CSF– and GM-CSF–stimulated donors.[29] Granulocyte transfusion has been suggested to result in more favorable response rates (33%–50%) in profoundly neutropenic patients by shortening the duration of neutropenia.[29]

■ Pulmonary Scedosporiosis

The genus *Scedosporium* comprises a group of filamentous fungi found ubiquitously in the environment. The two major human pathogenic species are *Scedosporium apiospermum*—the asexual state of *Pseudallescheria boydii*—and *Lomentospora prolificans* (formerly *Scedosporium prolificans* or *S. inflatum*).[27,28,30] Both of these species histologically resemble *Aspergillus* spp. with hyphae that are septate and branching at acute angles. Although *Scedosporium* infections can occasionally occur in immunocompetent individuals, the overall incidence has increased over the past decade because of improved diagnostic modalities and the expanding population of immunocompromised individuals. These fungi can cause fatal angioinvasive infections in immunocompromised hosts that manifest with sinopulmonary, central nervous system, osteoarticular, ocular, endovascular, and lymphocutaneous involvement.[27,28,30] Disseminated infection is associated with high (>75%) mortality rates. *Scedosporium* spp. are known to be remarkably resistant to most conventional antifungals, such as AMB; treatment with newer triazoles, such as voriconazole, appears to be more efficacious.[27,28,30,31]

Spores of *Scedosporium* spp. enter the respiratory tract by inhalation and the skin by direct inoculation to areas of trauma. Germination of conidia results in hyphal invasion in tissue with the potential to disseminate hematogenously to distant anatomic sites. Similar to *Fusarium* spp., dissemination may be facilitated by the ability of *Scedosporium* spp. to undergo adventitious sporulation in vivo. In general, strains of *Lomentospora prolificans* are more virulent than strains of *S. apiospermum*. *Lomentospora prolificans* produces melanin, which may be an important virulence factor contributing to in vivo protection against host defense mechanisms.[27,28,30]

Patients with AIDS, congenital or acquired immunodeficiency, or hematologic malignancies as well as recipients of stem cell and solid-organ transplants and those receiving antineoplastic or immunosuppressive medications are especially susceptible to these filamentous molds.[27,28,30] In these immunocompromised individuals, sinopulmonary disease with hematogenous dissemination to various organs most often occurs. Of interest, a recent review of 189 cases of pulmonary scedosporiosis reported that 11% of all cases were in immunocompetent patients following near-drowning. This association implies the higher virulence of *Scedosporium* spp. compared to other opportunistic molds.[27,28,30]

The spectrum of pulmonary scedosporiosis largely mimics aspergillosis, ranging from respiratory tract colonization, to allergic bronchopulmonary hypersensitivity, to saprophytic fungus ball formation in pre-existing pulmonary cavities, and, finally, to invasive pulmonary or disseminated scedosporiosis.[27,28,30] Invasive disease without pre-existing lung tissue damage caused by *S. apiospermum* generally occurs only in immunocompromised hosts during or immediately after periods of prolonged neutropenia or with intensification of immunosuppression, and fever is the most common clinical presentation. Onset of infection may also be manifested by pulmonary symptoms, maculopapular skin lesions that later may become necrotic, myalgias, and central nervous system and other organ involvement.[27] On rare occasions, pulmonary infections that spread to involve the central nervous system are reported in immunocompetent individuals after massive inoculation with *S. apiospermum* by aspiration of polluted water.[27] Fungemia is diagnosed in more than two-thirds of patients with disseminated *Lomentospora prolificans* and *S. apiospermum* infection. The radiographic appearance of pulmonary infections caused by *S. apiospermum* and *Lomentospora prolificans* is essentially indistinguishable from that of IPA. Because no radiographic findings are truly pathognomonic for *Scedosporium* infections, diagnosis relies on prompt histopathologic and microbiologic evaluation.

Histopathological features of *Scedosporium* spp. in tissue sections can be confused with those of other fungi that have acute-angle–branching septate hyphae. The melanin-specific Fontana–Masson stain may be used to confirm the presence of dematiaceous hyphae of *Lomentospora prolificans* in tissue.[27,28,30] Nevertheless, definitive diagnosis requires fungal culture and is crucial for antifungal susceptibility testing.

In general, *Lomentospora prolificans* is resistant to all clinically available antifungal agents, whereas *S. apiospermum* may be susceptible to miconazole, voriconazole, and posaconazole.[27,28,30] Both species are inherently resistant to the polyenes, including AMB. Data from clinical studies are limited. In a multicenter study of voriconazole administered as salvage therapy for scedosporiosis, the overall response rate of voriconazole for scedosporiosis outcomes of voriconazole therapy for *S. apiospermum* (33%) was somewhat better than that for *Lomentospora prolificans* (25%).[27,28,30]

Severe *Lomentospora prolificans* infections have been successfully treated with a combination of voriconazole and terbinafine.[27,28,30] In combination with azoles, terbinafine, an allylamine that blocks squalene epoxidase in the ergosterol synthesis pathway, has demonstrated synergistic interactions in vitro against clinical isolates of *S. prolificans*. Limited experience in patients with disseminated *Lomentospora prolificans* suggests that the combination of voriconazole and terbinafine is a legitimate treatment option, although the unfavorable pharmacokinetic characteristics of terbinafine preclude use as monotherapy.

Surgical debridement in cases of pulmonary scedosporiosis should be considered, especially for abscess drainage as well as for localized infections. In general, neutrophil recovery has been associated with an improved prognosis. IFN-γ and GM-CSF have been shown to enhance neutrophil oxidative mechanisms of killing against *S. prolificans* hyphae.[27,28,30] Although clinical data are scarce, in view of the dismal prognosis for patients with *Scedosporium* infections, immunomodulating therapy, including G-CSF, GM-CSF, IFN-γ, and primed white blood cell transfusions, should be considered as an adjunct treatment modality for these infections.[27,28,30]

CHAPTER 133

Cryptococcosis and the Endemic Mycoses: *Histoplasma*, *Blastomyces*, and *Coccidioides*

Marwan M. Azar
Nathan C. Bahr
Joshua Malo
Chadi A. Hage

INTRODUCTION

The dimorphic fungi *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis/posadasii* and the yeast *Cryptococcus neoformans* share important epidemiologic, mycologic, and clinical characteristics. With the exception of *Cryptococcus neoformans* var. *neoformans*, which exhibits no strong geographic predilection, these fungi are found in the soil and other environmental niches of certain endemic regions within the United States, particularly the Mississippi and Ohio River valleys for *H. capsulatum* and *B. dermatitidis*, the Southwestern United States for *C. posadasii/immitis*, and the Pacific Northwest for *Cryptococcus neoformans* var. *gattii* (Fig. 133-1). Beyond the United States, areas of high endemicity have been established across all six inhabited continents, lending global significance to these fungal pathogens (Fig. 133-1).[1] Additionally, due to global warming, anthropomorphic land utilization, and a world that is increasingly interconnected by the mass migration of people and goods, the geographic extent and epidemiology of endemic fungi are changing. Infection most commonly follows inhalation of aerosolized infectious particles when sites containing the organism are disturbed. Within the human host, these pathogens exist in yeast form and must be distinguished from other pathogenic yeast and from one another based on mycologic characteristics including size, wall thickness, and presence and type of budding, among others important features. Unlike many other fungi that cause disease only in immunocompromised hosts or in those with disrupted mucosal or skin barriers, the dimorphic fungi and *Cryptococcus*, especially *Cryptococcus neoformans* var. *gattii*, can lead to local and disseminated disease in the immunocompetent host. Indeed, the majority of those hospitalized due to infection with endemic mycoses in the United States and up to 20% of HIV-negative patients with *Cryptococcus* infection have no identifiable immunologic deficits.[2] In endemic areas, dimorphic fungal pathogens account for up to 30% of community-acquired pneumonia and respiratory manifestations mimic those of bacterial pneumonia leading to antibiotic misuse, diagnostic delays, and increased morbidity and mortality.[3] Both *Cryptococcus* and the endemic fungi can lead to a wide spectrum of pulmonary manifestations ranging from subclinical and mild respiratory symptoms to acute, subacute, and chronic pneumonias, mediastinal involvement, and acute respiratory failure as well as a variety of pulmonary infiltrates, including nodules, consolidations, cavities, and ground-glass opacities among others. These presentations must be distinguished from other infectious and noninfectious pulmonary processes such as bacterial pneumonia, tuberculosis, lung cancer, and sarcoidosis that may present similarly. Dissemination outside the lungs occurs more commonly in immunosuppressed hosts and is associated with high mortality. In the United States, direct healthcare costs from histoplasmosis, blastomycosis, and coccidioidomycosis alone approach $500 million annually, emphasizing the devastating impact of endemic mycoses and the need for increased awareness, early diagnosis, and effective treatment modalities.[4]

CRYPTOCOCCAL INFECTIONS

Cryptococcus neoformans is an encapsulated yeast that has a worldwide distribution. Cryptococcosis occurs when *C. neoformans* is inhaled and, after gaining entry into lungs, spreads hematogenously. Although cryptococcal meningoencephalitis is the most commonly diagnosed and most severe form of cryptococcosis, *C. neoformans* may infect numerous other systems, and the spectrum of disease varies from asymptomatic pulmonary infection to critical illness, typically due to meningoencephalitis. In 2017, it was estimated that 6% (95% confidence interval [CI], 5.8–6.2) of HIV-positive persons with a CD4 T cell count <100 cells/mm^3 had a positive cryptococcal blood antigen test, totaling 278,000 (95% CI, 195,500–340,600) cases of cryptococcosis with a positive blood antigen test and 223,100 (95% CI, 150,600–340,600) cases of cryptococcal meningitis.[5] Although most cases are associated with HIV, a number of other immune-suppressing conditions confer susceptibility to cryptococcosis, and disease may also develop in persons not known to have underlying immune suppression.[2,6,7] Mortality related to cryptococcal meningoencephalitis ranges from ~20% to as high at 70% and is heavily influenced by local resources, antifungal therapy selection, and supportive care.[8]

■ Epidemiology

C. neoformans serotypes A and D are most common in North America and Europe and are often associated with bird droppings or vegetation. Serotypes B and C are classified as *C. neoformans* var.

gattii and are endemic to Australia where they are classically associated with eucalyptus trees as well as other tropical and subtropical regions.[9] Numerous outbreaks have now been reported in nontropical regions such as the pacific northwest of North America.[10] Aside from those related to *C. neoformans* var. *gattii* in recent years, outbreaks are rare. Person-to-person transmission has not been documented. While persons living with HIV (PLWH), particularly those with CD4 T cell counts <100 cells/mm^3, are at high risk for cryptococcosis, numerous other groups are at high risk, including those taking immunosuppressive medications such as tumor necrosis factor (TNF) inhibitors, ibrutinib and other tyrosine kinase inhibitors, corticosteroids, and transplant-related immune suppressive medications, as well as those with other immunosuppressive conditions such as cirrhosis, lymphoreticular malignancies, and anti–granulocyte-monocyte colony-stimulating factor antibodies.[2,6,7,11] Persons without known immunosuppressive conditions are less commonly affected by cryptococcosis.[2]

■ Mycology

C. neoformans is characterized by its thick polysaccharide capsule, which can vary from 1 to 30 or more μm, with the yeast itself measuring 4 to 6 μm in diameter (Table 133-1, Fig. 133-2). The capsule tends to be smaller in the environment, which allows the yeast to reach terminal airways when inhaled. *C. neoformans* grows readily in fungal media, allowing isolation usually in less than 48 h. *C. neoformans* can be identified by biochemical tests or

DNA probes, and four serotypes (A, B, C, D) have been described, as noted above.

Pathogenesis

C. neoformans is generally acquired via inhalation although direct inoculation of skin or soft tissues can occur as well. After inhalation, yeast may reach as far as the pulmonary alveoli despite typical physical immune defense mechanisms, such as airflow turbulence, the epithelial mucosal barrier, and mucociliary transport.[12] The innate immune response to *C. neoformans* includes alveolar macrophages, dendritic cells, natural killer cells, and the complement system.[12] In some cases granulomas form in the lungs, sequestering the organisms, and latent infection is established.

In addition, CD4+ T helper cells and a Th1 type immune response, where interferon γ (IFN-γ) plays a crucial role, are particularly important for control of cryptococcosis.[12,13] One mechanism used to evade host destruction by *C. neoformans* yeast is to promote an imbalanced immune response, skewed toward Th2. Progressive disease may occur in those with impaired cellular immunity, highlighting the close linkage of severe cryptococcosis, particularly cryptococcal meningitis, with advanced HIV.[12,13] Proposed mechanisms for central nervous system (CNS) invasion include the "trojan horse" model in which macrophages infected with *Cryptococcus* cross the blood–brain barrier (BBB) via transcytosis through the interstitial spaces of the BBB, or paracytosis, by which proteases help *Cryptococcus* to digest cells in order to cross the BBB.[14]

Clinical Findings

Cryptococcal infection has a broad range of outcomes. In persons with normal immune systems, asymptomatic or self-limited

pulmonary infections are most common. In persons with immune deficits (particularly those within the adaptive immune system, such as PLWH), disease may be much more severe. In this population, meningoencephalitis is the most commonly recognized manifestation of cryptococcosis and the most common cause of death, although hematogenous dissemination to nearly every tissue has been reported.

Pulmonary

The lung serves as the primary portal of entry for cryptococcal infections. In hosts without immune-compromising conditions, isolated asymptomatic pulmonary infection is common. Evidence of prior infection may be noted on subsequent imaging, but findings such as nodular infiltrates (Fig. 133-3) are not specific enough to point to *Cryptococcus* as the culprit. Symptoms, when they occur, are nonspecific and may include dyspnea, cough, fever, and chest pain.[12] Symptoms generally resolve spontaneously in those who truly have a normal immune system, although progression of pulmonary findings, concurrent meningoencephalitis, or concurrent disseminated disease all occur in some cases.

Cryptococcosis in immunocompromised hosts is more likely to cause symptomatic pulmonary disease, although symptoms are similarly nonspecific, as noted above. Imaging findings may include diffuse interstitial or patchy alveolar infiltrations. In persons with less severe immune deficits, patchy alveolar or nodular infiltrates may occur (Fig. 133-3). Other rarer imaging findings may include cavitary disease, cryptococcoma, mediastinal adenopathy, and pleural effusion. The "halo sign," often considered classic for

aspergillosis, may occur with cryptococcosis as well.[12] Concomitant meningoencephalitis or dissemination is more likely to occur with more severe immune compromise; mortality is at least 20% in many settings if meningoencephalitis develops.[8]

Meningoencephalitis

Meningoencephalitis is the most severe and commonly diagnosed manifestation of cryptococcosis. Generally, cryptococcal meningoencephalitis presents as a subacute disease with symptoms worsening over 2 to 4 weeks, but a more rapid presentation may occur with severe immunodeficiency. Typical symptoms include headache, nausea, vomiting, meningismus, fever, and altered mentation; changes in mentation are associated with poor outcomes.[14] Focal neurologic abnormalities also occur, with sixth cranial nerve palsies being particularly common; seizures are seen in up to one-third of patients.[14,15] Elevated intracranial pressure is common, often persistent (even without clear symptoms), and if not managed properly, leads to poor outcomes.[15] Repeated lumbar punctures are commonly required to reduce intracranial pressure.[16] Lumbar drains or ventriculoperitoneal shunts are needed on occasion. Intracranial cryptococcomas occur more rarely and are difficult to treat.

Other Sites of Dissemination

While meningoencephalitis and pulmonary cryptococcosis are most commonly diagnosed, disseminated cryptococcosis may involve nearly any organ in the body. Skin lesions are often umbilicated, resembling molluscum contagiosum, and can be an early clue to cryptococcosis. Additional sites of involvement frequently reported include the liver, spleen, kidneys, lymph nodes, bone marrow, eyes, and bones. The prostate has been recognized as a site of cryptococcal infection and persistence after acute infection.[17] However, nearly every organ has been described as susceptible to cryptococcal disease; autopsy studies have been particularly helpful in describing disease distribution.[18]

Immune Reconstitution Syndrome

Immune reconstitution inflammatory syndrome (IRIS) commonly complicates HIV-associated cryptococcal meningitis. Although cryptococcal IRIS may occur in conditions as broadly disparate as treatment with granulocyte-colony stimulating factor and the early postpartum period, it is much more common with HIV infection.[19–21] Generally, IRIS is categorized as either "paradoxical" or "unmasking."

In HIV-associated cryptococcal meningitis, paradoxical IRIS is characterized by the patient having been diagnosed with cryptococcal meningitis, having an appropriate clinical response to treatment, and having a recurrence or worsening of symptoms after beginning antiretroviral therapy. In the same context, unmasking IRIS refers to starting antiretroviral therapy (ART) without a known diagnosis (or, presumably, symptoms) of cryptococcal meningitis, but subsequently, after starting ART, having a rapid onset of symptoms consistent with cryptococcal meningitis, and thereafter, establishment of the diagnosis. Both versions of IRIS are generally characterized by an exaggerated and often disorganized immune response.[19]

Paradoxical cryptococcal IRIS is characterized by pre-ART elevations in Th2 and Th17 type cytokines, such as interleukin (IL)-17 and IL-4, decreases in proinflammatory cytokines, such as TNF-α and granulocyte colony–stimulating factor, and higher titers of serum and cerebrospinal fluid (CSF) cryptococcal antigen (CrAg).[19,22] Clinically, IRIS mimics the presentation of the underlying phenomenon; symptoms are similar to cryptococcal meningitis, but the onset of symptoms after treatment initiation should raise the possibility of IRIS. Cryptococcal meningitis–associated IRIS has higher mortality than does IRIS outside of the CNS due to the inflexibility of the anatomic location. To prevent IRIS to cryptococcal meningitis in patients with newly diagnosed HIV, ART initiation should be delayed for 4 to 5 weeks (as opposed to immediately starting ART, which is otherwise recommended).[23] Prevention of unmasking IRIS is accomplished by screening for CrAg in asymptomatic individuals with CD4+ counts <100 cells/mm^3 prior to starting ART. This practice has become standard of care in many parts of the world and is recommended by the World Health Organization.

Diagnosis

A variety of modalities may be used in establishing a diagnosis of cryptococcal infection.

Pneumonia

Diagnosis of cryptococcal pneumonia can be difficult. In general, the fungal burden is higher in PLWH, so detection of the yeast is more easily achieved. Dissemination outside the lungs is more common in PLWH, so extrapulmonary disease should be investigated. Serum CrAg is less sensitive for pneumonia than for meningitis. Although less reliable in isolated pulmonary disease in those without HIV (as low as 23% in one study), relatively high sensitivities are achieved in PLWH, with findings as high as 100% in one small study (Table 133-2).[24–27] Bronchoalveolar lavage (BAL) CrAg use has been reported but is not routinely done. Regardless, a negative CrAg alone cannot rule out isolated pulmonary cryptococcal disease.

When biopsy is indicated, cytology and/or histopathology may be more sensitive in people without HIV, although the test is more invasive.[24–27] *C. neoformans* is most recognizable in cytology or histopathology by its large polysaccharide (Fig. 133-2). Numerous stains, including Gomori methenamine silver (GMS), periodic acid–Schiff (PAS), and India ink can readily identify *C. neoformans* yeast. Special stains for cryptococcosis include the Fontana-Masson stain, which stains the melanized cryptococcal cell wall, and the mucicarmine stain, which highlights the cryptococcal capsule. These stains can be useful in differentiating *C. neoformans* from similarly sized yeasts like *B. dermatitidis*.[28] Culture of sputum or BAL fluid may achieve similar sensitivities but may require up to 2 weeks to achieve a diagnosis.[25–27] Colonization of the airway may occur, so the diagnosis should be considered if an unexpected positive culture or histopathology result occurs.

Screening for CNS Disease in Those with Pulmonary Disease

The patient's net state of immunosuppression is crucial in understanding cryptococcal CrAg testing in particular. In PLWH with pulmonary cryptococcosis, positive serum CrAg often reflects dissemination or, at least, a high fungal burden with antigen spilling into the circulation. Thus, in such situations, CNS disease must be considered. CSF examination is indicated if the patient has any symptoms of meningitis or CNS involvement. Most experts also recommend lumbar puncture in PLWH with a positive serum CrAg test and/or evidence of pulmonary cryptococcosis, regardless of symptoms.[16,29] A positive serum CrAg is associated with a significant risk of meningitis in solid organ transplant recipients.[30] Therefore, symptoms and signs of meningitis should be investigated and a lumbar puncture considered.[31] On the other hand, for

TABLE 133-2 Diagnostic Studies in Cryptococcosis (Percent Positive Assays)

putatively normal hosts with pulmonary cryptococcosis and no evidence of CNS disease, lumbar puncture is not required.

Meningoencephalitis

Although CSF culture has traditionally been the gold standard for the diagnosis of cryptococcal meningitis, CrAg is likely more sensitive and is much more rapid (~10 minutes versus up to 2 weeks).[29] The cryptococcal lateral flow assay (LFA) CrAG (IMMY Inc, Norman, OK, USA) is an improvement on the traditional latex agglutination (LA) CrAg in terms of performance (Table 133-2); the test is inexpensive, rapid, and widely available, and does not require cold-chain storage. Sensitivity of LFA for CNS disease in PLWH is 99.3% versus 97.0% for LA, 94.2% for culture, and 86.1% for India ink.[29] Although widely available and cheap, India ink testing is not helpful unless antigen testing is unavailable. In persons without HIV, performance of CSF CrAg is still excellent, although it is slightly less sensitive than for PLWH (Table 133-2).

Serum CrAg LFA testing is a highly sensitive screening tool for cryptococcal meningitis. While the presence of serum CrAg LFA doesn't confirm meningitis, it does confirm the diagnosis of cryptococcosis. One study in Uganda found that of 149 persons with positive serum CrAg, 138 had a positive CSF CrAg, while the remaining 11 were determined to have cryptococcal disease (no false positives).[32] Of note, the study found 100% agreement among plasma, serum, and fingerstick assessments of the CrAg LFA.[32] Importantly, the CrAg LFA is not an infallible test and is susceptible to false negative results due to "post-zone" effects at extremely high titers—an issue that can be remedied with serial dilution.[33] False-positive tests in persons without HIV are also a concern when dealing with low titers.[34]

In persons with a prior diagnosis of cryptococcal meningitis, decay of antigen in the blood or CSF is unpredictable; hence, following serial antigen titers is of uncertain utility. Furthermore, in a person with a recurrence of symptoms after treatment, antigen testing may not be helpful, as it may remain positive. In these situations, treatment failure must be strongly considered while awaiting culture results.

Two diagnostic tests, CSF (1–3)-B-D-Glucan and the FilmArray CSF panel (BioFire, Salt Lake City, UT, USA), which are not as sensitive as CrAg for diagnosis of cryptococcosis, may have some utility in this setting, as both tests decay more rapidly than CrAg.[35–37] Although neither test should be considered a first-line test for diagnosis of cryptococcal meningitis, (1–3)-B-D-Glucan may indeed be detectable in cryptococcal meningitis, despite the poor sensitivity of serum (1–3)-B-D-Glucan for cryptococcal infection.[37,38]

CSF lactate may be utilized as a prognostic marker of cryptococcal meningitis severity and mortality in the setting of HIV. In a study of 317 Ugandan patients with PLWH with cryptococcal meningitis, elevated CSF lactate levels were associated with altered mental status, seizures, increased CSF opening pressures, and death.[39]

Treatment

Persons with symptomatic pulmonary disease or who are asymptomatic and immune compromised, and all persons with meningoencephalitis or disseminated disease require treatment (Table 133-3).[16] Patients with profound immune suppression related to HIV and "asymptomatic antigenemia" also should be treated.[40] Whether such strategies make sense for immunosuppressed, non-HIV populations is less clear at this time. If treatment is not initiated in an asymptomatic person with pulmonary cryptococcosis without immune compromise or symptoms, he or she should be observed closely. Any increase in lesion size or number on imaging, or development of symptoms, should be considered an indication to start treatment. A situation where treatment can truly be avoided altogether is rare.

TABLE 133-3 Treatment Recommendations for Cryptococcosis Syndromes

Syndrome	Recommendation
Pneumonia (mild–moderate)	Fluconazole 400 mg daily for 6 to 12 months
Pneumonia (severe)	Same as for meningitis
Meningitis (IDSA 2010)	**Induction**: Amphotericin B deoxycholate (0.7–1.0 mg/kg/day) or liposomal amphotericin B (3–4 mg/kg/day) or amphotericin B lipid complex (5 mg/kg/day) plus flucytosine (100 mg/kg/day divided into four doses) for at least 2 weeks (4 weeks for non-HIV, nontransplant patients) **Consolidation**: Fluconazole 400 mg daily × 8 weeks **Maintenance:** Fluconazole 200 mg daily for at least 12 months total of therapy
Meningitis (WHO 2018)	**Induction**: Amphotericin B (1.0 mg/kg/day) plus flucytosine (100 mg/kg/ day, divided into four doses per day) for 1 week followed by 7 days of fluconazole 1200 mg daily **Consolidation**: Fluconazole 800 mg daily × 8 weeks **Maintenance:** Fluconazole 200 mg daily for at least 12 months total of therapy

Pneumonia

Assuming there is no CNS disease, therapy for mild to moderate pulmonary disease consists of fluconazole, 400 mg daily for 6 to 12 months.[16] The workup for sites of dissemination, including CNS, disease should be more intensive in those with suppressed immune systems. In those with severe disease, treatment should begin with amphotericin-based therapy, as for meningeal disease (see below).[16] Posaconazole, voriconazole, isavuconazole, and itraconazole are alternatives with minimal supporting evidence for their use if administration of fluconazole is not possible.

Meningitis

Currently, cryptococcal meningitis therapy is based on the combination of amphotericin B and flucytosine induction, followed by a longer consolidation regimen of high-dose fluconazole, and, finally, a long-term, lower-dose course of fluconazole for secondary prophylaxis.[16] In PLWH, the 2010 Infectious Disease Society of America (IDSA) guidelines recommend amphotericin B deoxycholate (0.7–1.0 mg/kg/d) or liposomal amphotericin B (3–4 mg/kg/day) or amphotericin B lipid complex (5 mg/kg/day), plus flucytosine (100 mg/kg/day divided into four doses) for at least 2 weeks, followed by fluconazole, 400 mg daily × 8 weeks, followed by fluconazole, 200 mg daily for secondary prophylaxis until the CD4 count is >100 cells/mm^3 and viral load suppressed for at least 3 months (at least 12 months total of therapy).[16] Recommendations for transplant recipients are similar except that liposomal or lipid complex formulations of amphotericin are explicitly preferred over amphotericin b deoxycholate.[16] Additionally, immunosuppression should be reduced concomitantly with antifungal treatment to improve therapeutic response and reduce the likelihood of relapse. Maintenance therapy should be continued for 6 to 12 months, with careful monitoring after stopping fluconazole. If symptoms recur, lifelong maintenance therapy may be required.

In non-HIV, nontransplant persons with cryptococcal meningitis, a 4-week induction period is recommended.[16] The lipid preparations of amphotericin are generally less toxic. Fluconazole monotherapy at doses as high as 1200 mg daily is used in some parts of the world where amphotericin or flucytosine are not available. However, whenever possible, amphotericin-based combination therapies are preferred, given that mortality with fluconazole monotherapy is up to 70% in some settings.[8,41]

Since the 2010 IDSA guidelines were published, large clinical trials have been completed, particularly those related to HIV-associated cryptococcal meningitis. Molloy et al. published the ACTA trial in 2018,[42] a landmark, large ($n = 721$), open-label, randomized study of HIV-associated cryptococcal meningitis at nine African centers. Participants were assigned to induction therapy of fluconazole, 1200 mg daily, plus flucytosine, 100 mg/kg/day × 2 weeks, versus amphotericin B deoxycholate, 1 mg/kg/day for 1 or 2 weeks. The amphotericin arms had fluconazole or flucytosine (at the same doses as above) randomly assigned as partner drugs, for an effective total of five arms. Ten-week mortality was lowest when one week of amphotericin B was paired with flucytosine (24%), interestingly, followed by fluconazole plus flucytosine (35%).[42] Two weeks of amphotericin led to more adverse events, likely contributing to greater attrition and higher overall mortality. Flucytosine was clearly superior to fluconazole as a combination agent for amphotericin B,[42] a particularly notable finding, given difficulties in accessing flucytosine in much of the world.[8] Based on these findings and systematic reviews of other published data,[43] the World Health Organization now recommends 7 days of amphotericin B plus flucytosine, followed by 7 days of fluconazole, 1200 mg daily as induction therapy; if amphotericin (or necessary adjunctive treatments and monitoring capability) is unavailable, oral flucytosine plus fluconazole for 2 weeks is an alternative.[44] The World Health Organization also recommends a higher dose (800 mg daily) of fluconazole for consolidation based primarily on expert opinion.[44]

In 2019, an important phase 2 study evaluated the effectiveness of single-dose liposomal amphotericin (10 mg/kg) compared with daily infusions of 3 mg/kg (both with 14 days of high-dose oral fluconazole) for HIV-associated cryptococcal meningitis in Tanzania. Among 80 participants, noninferiority was achieved for the mean rate of fungal culture clearance.[45] These findings are now being further examined in a large, phase 3, open-label study in five African countries, where a single dose of liposomal amphotericin (10 mg/kg) plus 14 days of fluconazole (1200 mg daily) and flucytosine (100 mg/kg/daily) will be compared to the new standard of care per World Health Organization guidelines (7 days of amphotericin deoxycholate [1 mg/kg daily] plus flucytosine [100 mg/kg daily], followed by 7 days of fluconazole [1200 mg daily]); this trial is ongoing.[46] When IDSA revisits cryptococcosis guidelines, changes to the induction regimen should be a strong consideration.

In addition to antifungal treatment, intracranial pressure should be closely monitored. If CSF opening pressure is greater than 25 cm H_2O, repeat lumbar punctures should be performed to drain CSF sufficiently to relieve intracranial pressure by 50% or to $<$20 cm H_2O.[16]

Additional Considerations for Treatment of Cryptococcal Meningitis

In 2014, Boulware et al. published the landmark COAT trial, which showed that in ART-naïve individuals with cryptococcal meningitis, starting ART within 1 to 2 weeks of beginning cryptococcal meningitis treatment carried a significantly higher risk of 26-week mortality (45%) than did starting ART after 5 weeks (30%); the hazard ratio for death was 1.73 (95% CI, 1.06–2.82; $p = 0.03$).[23] Most of the excess deaths in the early ART arm occurred within 2 to 5 weeks from diagnosis. A later analysis of this study found that early ART was associated with CSF pleocytosis and macrophage activation, perhaps giving insight into immune mechanisms related to increased mortality.[47] Thus, the standard of care is to wait 5 weeks from the start of induction therapy to start ART in ART-naïve persons with cryptococcal meningitis.

All amphotericin formulations are associated with nephrotoxicity, hypokalemia, and hypomagnesemia. These issues are particularly pronounced with amphotericin B deoxycholate. In 2014, Bahr et al. reduced treatment mortality compared to historic controls by implementing a uniform protocol of potassium and magnesium monitoring and universal supplementation, and additional standardized replacement when necessary.[48] Compared with historic controls, 14-day mortality improved from 62% to 78% with the universal electrolyte protocol.[48] Electrolyte monitoring and replacement, although considered routine in many locations, are not routinely available in many settings and are now part of the World Health Organization treatment recommendations for HIV-associated cryptococcal meningitis.[44]

In addition to pharmacotherapy, management of intracranial pressure is crucial. Use of therapeutic lumbar puncture is associated with improved survival.[49] Repeat lumbar punctures should be done routinely in the absence of contraindications. In some cases, where available, lumbar drain or ventriculoperitoneal shunts should be considered.[16]

Disseminated or Extrapulmonary Disease without Meningoencephalitis

There should be a high concern in persons with disseminated disease for meningitis until proven otherwise. Although rare, falsely negative CSF cryptococcal antigen testing does occur (at times due to the post-zone effect with massive fungal burden or, conversely, due to lower fungal burden in CSF, as in discrete CNS disease with cryptococcomas).[33] Thus, the safest route for the patient is likely to treat in most cases as if meningitis is present. The treatment principles related to meningitis above should be considered strongly in these situations.

Asymptomatic Antigenemia

One crucial strategy to prevent death due to cryptococcosis is to screen at-risk persons with serum CrAg. CrAg is present in 1% to 15% of asymptomatic PLWH and CD4 counts $<$100 cells/mm^3; one study from the United States found a positive rate of 2.9%.[29,50] Those with detectable CrAg and no evidence of meningitis should be treated preemptively with high-dose fluconazole.[29] One randomized controlled trial (RCT) in sub-Saharan Africa found a 28% survival benefit from this practice, which is now recommended by the World Health Organization and which has been found to be cost-effective in numerous settings.[44,51] Whether high-dose fluconazole is adequate treatment for this entity is unclear, and studies investigating amphotericin-based therapies in this setting are ongoing.

Role of Antifungal Resistance

C. neoformans resistance to fluconazole is of significant concern. In 2015, among 198 clinical isolates from Uganda, Smith et al. found the minimum inhibitory concentration (MIC) required to inhibit $>$50% of strains (MIC50) was 8 μg/mL and the MIC90 was 32 μg/mL; 31% of isolates had an MIC of ≥16 μg/mL (considered resistant in vitro). These findings were compared to an MIC50 of 4 μg/mL and an MIC90 of 8 μg/mL in isolates in two studies from 1998 to 1999, prior to widespread human use of fluconazole and agricultural use of azole fungicides.[52] The worsening resistance patterns are of significant concern and will only serve to worsen the already poor survival for cryptococcal meningitis treated with fluconazole monotherapy. Also of concern is be the potential for breakthrough fluconazole-resistant strains while on maintenance therapy.

Alternative Antifungal Agents

Alternatives to fluconazole include itraconazole, voriconazole, posaconazole, and isavuconazole. None of these agents appears to offer clear advantages over fluconazole, but they may be considerations as salvage therapy. Although *Cryptococcus* does produce relatively small amounts of (1–3)-B-D-Glucan, echinocandins are not active against *C. neoformans* in vitro and should not be considered as salvage therapy.[53]

Adjunctive Therapy

Adjunctive IFN-γ immunotherapy showed no mortality benefit when added to amphotericin B and flucytosine in a randomized controlled trial in patients with cryptococcal meningitis.[54] Generally, this therapy is not utilized, nor it is available in settings where cryptococcosis is most common. Of note, sertraline showed promising activity against *Cryptococcus* in vitro and in vivo. An open-label dose study showed faster clearance of *Cryptococcus* from the CSF when used in conjunction with amphotericin and high-dose fluconazole.[55,56] Unfortunately, a placebo-controlled RCT did not show benefit in mortality, so sertraline is not used to treat cryptococcal meningitis.[57] Similarly, there was significant interest in corticosteroids as an adjunctive therapy, given the frequency of IRIS and the drug's role in TB meningitis. Yet, a placebo-controlled RCT found that adjunctive dexamethasone not only did not improve mortality, but also increased adverse events and disability. Thus, outside of documented cryptococcal IRIS, dexamethasone is not recommended for cryptococcal meningitis.[58]

■ Prevention and Screening for Cryptococcosis

Broad antifungal prophylaxis is not currently recommended, even in persons with advanced HIV/AIDS. Rather, appropriate use of ART in all PLWH is the mainstay of cryptococcosis prevention in this setting. Secondary prevention by targeting screening for cryptococcal antigenemia in susceptible individuals is crucial and cost-effective, as discussed above. Such efforts have not been well studied in persons with other forms of immunosuppression. *Cryptococcus* is ubiquitous in the environment; avoidance of exposure is difficult, although avoiding bird droppings may be beneficial.

HISTOPLASMOSIS

Histoplasmosis is the most prevalent endemic mycosis in the Americas and a major cause of morbidity in patients who live in endemic areas.[59] Progressive disseminated histoplasmosis (PDH) is an important complication in patients with HIV/AIDS and those receiving immunosuppression for the prevention of transplant rejection[60] or treatment of inflammatory diseases,[61–63] as well as those with malignancies and immunodeficiency disorders.[64] Understanding of the clinical syndromes and untreated course of the infection is essential to the diagnosis and management of patients with histoplasmosis. Improved laboratory tests have made rapid diagnosis possible. Expanded treatment options are available using triazole antifungal agents and liposomal formulations of amphotericin B.

■ Epidemiology

H. capsulatum var. *capsulatum* is highly endemic in areas of North America,[65] (Fig. 133-1) especially in U.S. states bordering the Mississippi and Ohio river valleys, as well as a large part of Central and South America.[1,66] In French Guiana, histoplasmosis is so prevalent that it eclipses other opportunistic pathogens in frequency and is the most common AIDS-defining illness.[67] Clusters of infections are reported at increasing rates from areas outside the traditional endemic regions, including China, Thailand, and India, as well as parts of Africa and Southern Europe.[1,68–70] African histoplasmosis, caused by *H. capsulatum* var. *duboisii,* occurs exclusively in Africa, particularly in Central and Western Africa and Madagascar.[71] Bird and bat excrement enhance growth of the organism by accelerating sporulation. Cases outside the endemic regions may be acquired by exposure during travel, prior residence in endemic areas, or exposure to microfoci containing the organism within nonendemic areas. In endemic areas, between 10% and 90% of individuals exhibit histoplasmin skin test positivity as immune evidence of past histoplasmosis.[72]

■ Mycology

Histoplasma capsulatum grows as a mold in the soil and converts to a yeast in tissues (Fig. 133-2). Microconidia, measuring 2 to 4 μm in diameter, are the infectious particles in the mold phase of the organism. *H. capsulatum* also grows as a mold on fungal media at ambient temperature in the laboratory. Definitive identification of a mold as *H. capsulatum* is made by DNA probe or exoantigen detection. At temperatures above 35°C, *H. capsulatum* grows as a yeast, which is the pathogenic form found in the tissues. The yeast measures about 2 to 5 μm and exhibits narrow-based budding.

■ Pathogenesis

Infection develops when conidia are inhaled and germinate into yeast. In many cases primary infection is asymptomatic and goes undiagnosed. Clinical illness most often follows exogenous infection or reinfection. With the development of cell-mediated immunity during the first month following initial infection, IFN-γ and IL-12 activate macrophages to kill the fungus and halt progression of the disease.[73] In addition, TNF-α is very important for immune defense against *H. capsulatum.*[74,75] These defense mechanisms are sufficient to control the infection in immunocompetent individuals, accounting for the subclinical or self-limited course characteristic of acute histoplasmosis in the majority (90%) of individuals.

Reactivation of latent infection may account for some cases occurring in individuals with past histoplasmosis who become immunocompromised. Studies showing a low incidence of histoplasmosis following immunosuppression in children,[76] organ transplantation,[77] or treatment with TNF inhibitors,[61,63] however, suggest that reactivation is rare. Also, latency could not be demonstrated experimentally in calcified lung lesions identified as incidental findings at autopsy.[78]

■ Clinical Manifestations

The clinical manifestations and severity of histoplasmosis depend on the infectious inoculum, the immune state of the host, and the health status of the host's lungs.[79,80] Heavy exposure can cause severe illness, even in healthy subjects. Low-level exposure is more common, however, and usually causes asymptomatic infection or clinically self-limited infection. When the exposure occurs in a closed space such as a cave, the attack rate is relatively high (50%–100% with a mean of 74%) with symptomatic infections, even for healthy individuals.[81] The common self-limited presentations are acute and subacute pulmonary histoplasmosis, pericarditis, and rheumatologic syndromes.

Asymptomatic Infection

In endemic areas, up to 90% of residents exhibit histoplasmin skin test reactivity by age 20.[72] In most of these cases, infection was presumed to have been asymptomatic. Most asymptomatic cases are identified as an incidental finding on chest radiographs or computed tomography (CT) scans performed for other reasons. The most common findings are enlarged mediastinal or hilar lymph nodes or pulmonary nodules.[82] The main significance of such findings is the need to differentiate them from malignancy or tuberculosis.[83]

TABLE 133-4 Summary of Pulmonary and Mediastinal Histoplasmosis Syndromes

	Age (Years)	Disease Course	Chest Imaging Findings	Presence of Calcifications	Fistulization	Preferred Diagnostic Method	Treatment Indication
Pulmonary Histoplasmosis							
Acute	Any	1–2 weeks	Diffuse airspace disease, lymphadenopathy	No	No	*Histoplasma* antigen BAL cytopathology and culture	No, unless prolonged or severe illness
Subacute	Any	Weeks to months	Focal airspace disease, lymphadenopathy	No	No	*Histoplasma* serology *Histoplasma* antigen (low sensitivity) BAL cytopathology and culture	No, unless symptoms last >1 month
Chronic	>45	Months to years	Focal airspace disease, upper lobe cavitary, thick-walled bullae, underlying emphysema	Yes (calcifications)	Rare	*Histoplasma* serology BAL cytopathology and culture	Yes
Progressive disseminated	Any immunocompromised	1–2 weeks	Diffuse airspace opacities	No	No	*Histoplasma* antigen BAL cytopathology and culture Blood and bone marrow culture	Yes
Mediastinal Histoplasmosis							
Mediastinal adenitis	<20	Early complication	Homogenous mediastinal mass	No	No	*Histoplasma* serology	Obstruction of airway, esophagus, or vessels
Mediastinal granuloma	>2	Early or late complication	Heterogenous mediastinal mass	Yes	Possible (to bronchi, esophagus)	*Histoplasma* serology	Obstruction, fistula, superinfection, persistent pain
Mediastinal fibrosis	>10, usually 20–30	Late complication	Homogenous mediastinal mass obstructing nearby airways, esophagus, or vessels	Yes (extensive)	No	*Histoplasma* serology	Recurrent hemoptysis, invasion/obstruction of airways, esophagus, or vessels

Asymptomatic infection also may be identified by demonstration of seropositivity during evaluation of another condition.

Pulmonary Syndromes

A variety of pulmonary syndromes may be seen with histoplasmosis.[80] They are considered below and in Table 133-4.

Acute Pulmonary Histoplasmosis Following heavy fungal exposure, patients present with diffuse pulmonary involvement often causing respiratory compromise.[71,80] Chest radiographs usually show diffuse interstitial, reticulonodular infiltrates, nodular, or patchy airspace disease, but a miliary pattern suggestive of hematogenous dissemination may be seen (Fig. 133-4). Initial radiographs may appear normal, evolving to show infiltrates over the next few weeks. Mediastinal adenopathy is common. Extrapulmonary dissemination occurs in about 40% of cases.[84] While patients may recover without therapy,[85] convalescence may be slow,[86] respiratory failure may develop,[87] and some infections may be fatal, especially after a heavy inoculum of infection.[87,88]

Subacute Pulmonary Histoplasmosis This syndrome presents subacutely and is most likely due to exposure to a smaller fungal inoculum.[80,89] Patients present with fever, cough, and chest pain. Chest radiographs often show mediastinal lymphadenopathy with patchy infiltrates. Most patients recover in a few weeks, but some experience persistent fatigue.

Chronic Pulmonary Histoplasmosis Chronic pulmonary histoplasmosis occurs in patients with underlying lung disease and is characterized by persistent or recurrent pulmonary symptoms, progressive lung infiltrates, fibrosis, and cavitation.[90–92] Upper lobe infiltrates and cavities are characteristic, resembling the findings of pulmonary tuberculosis. Progression is manifested by cavity enlargement, formation of new cavities, spread to other areas of the lungs, and formation of bronchopleural fistulae. Bacterial pneumonia, chronic *pulmonary aspergillosis*, and malignancy must also be considered in evaluation of new masses or infiltrates.

Nodules Nodules from histoplasmosis must be differentiated from malignancy.[83,93] Calcification suggests histoplasmosis but does not exclude malignancy. Conversely, the absence of calcification does not exclude histoplasmosis. Positive positron emission tomography (PET) scan, as seen with malignancy, is common in histoplasmosis. Rarely, nodules may cavitate, but cavitation does not necessarily represent development of chronic pulmonary histoplasmosis and does not require therapy. Nodules also may rarely enlarge (up to 2 mm per year), but slow enlargement is not caused by progressive infection and is not a basis for treatment on its

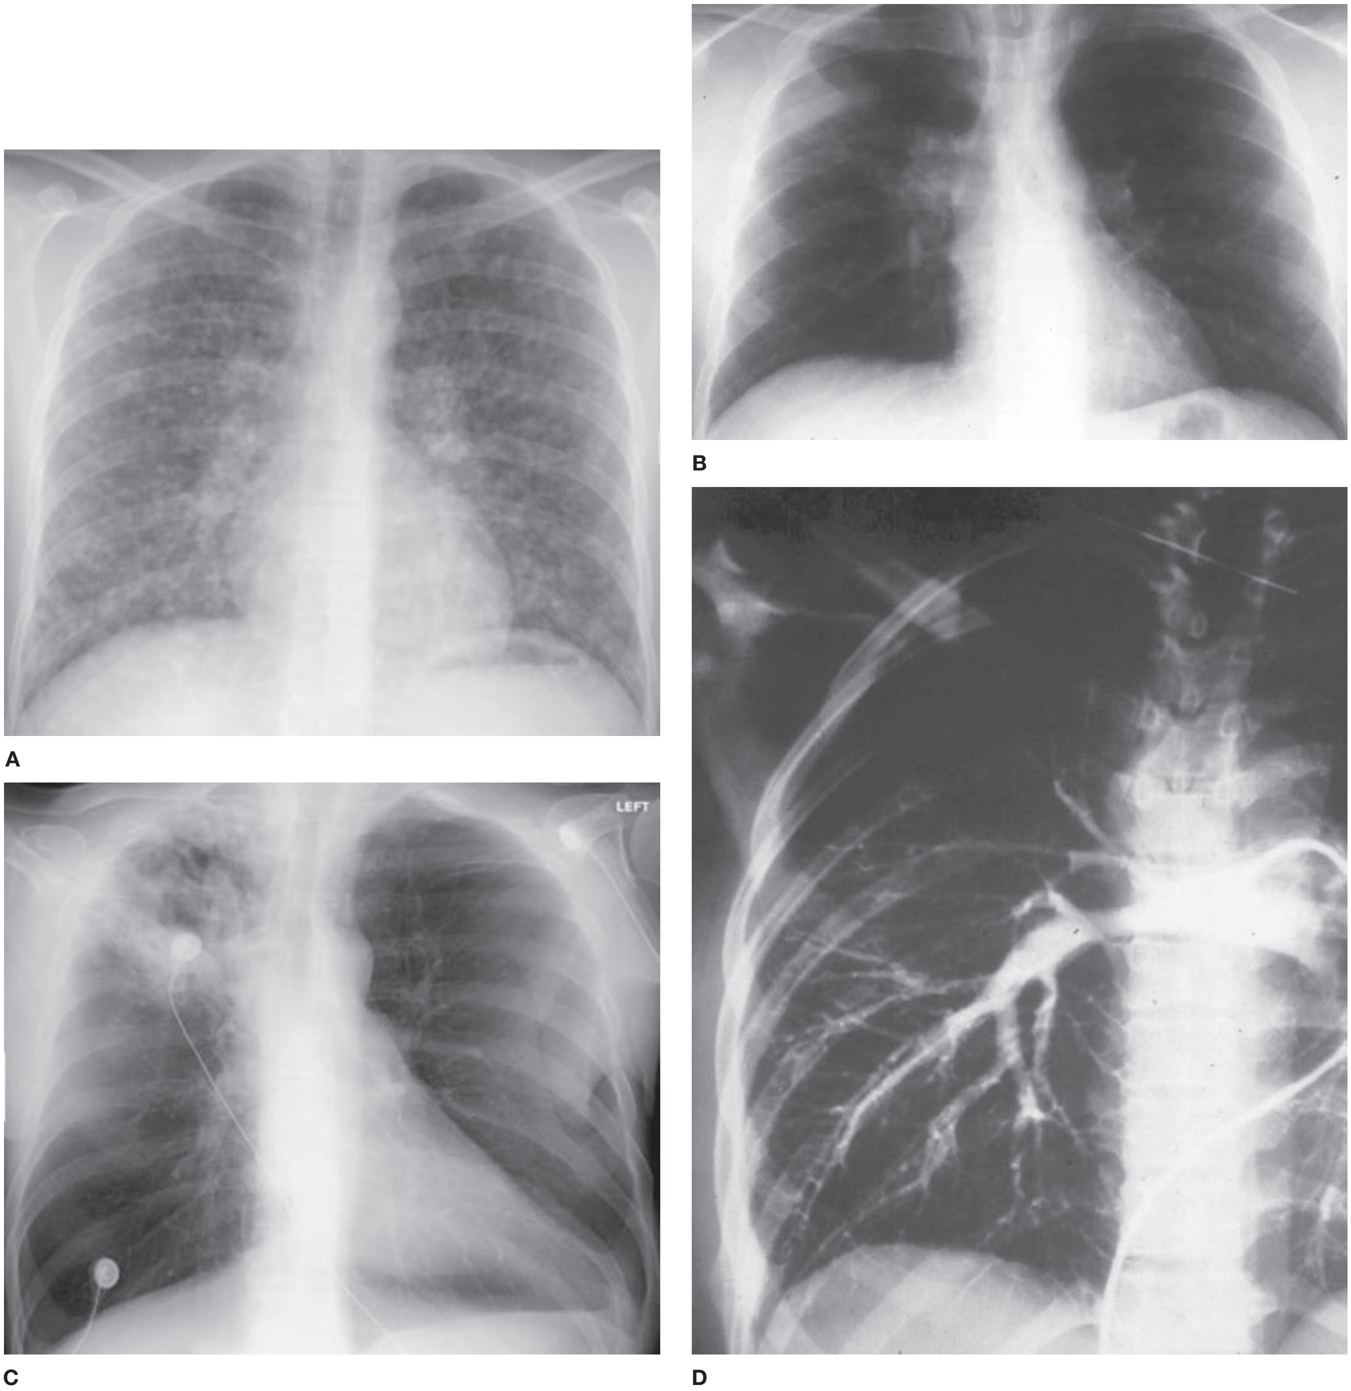

Figure 133-4 **A.** Chest radiograph of acute diffuse histoplasmosis after large inoculum exposure. **B.** Chest radiograph of subacute histoplasmosis with mediastinal adenopathy. **C.** Chest radiograph of cavitary histoplasmosis. **D.** Pulmonary arteriogram showing obstruction of pulmonary artery to right upper lung caused by fibrosing mediastinitis.

own.[94] Calcification occurs in the necrotic center and surrounding fibrous tissue.

Broncholithiasis Lymph nodes and pulmonary granulomas calcify and may erode into adjacent bronchi causing hemoptysis or obstruction.[82] Patients may expectorate stone-like particles of tissue and experience recurrent and severe hemoptysis, bronchial obstruction, or tracheoesophageal fistulae.

Relationship to Sarcoidosis Sarcoidosis and histoplasmosis share several clinical and radiographic findings.[82] Angiotensin-converting enzyme (ACE), sedimentation rate, C-reactive protein, and immunoglobulin elevations occur in both conditions.[95] Noncaseating granulomas can be seen with both, and caseation, which is more typical of histoplasmosis, may also occurs in sarcoidosis. Histoplasmosis must be excluded before the diagnosis of sarcoidosis is confirmed, to prevent administration of immunosuppressive therapy to patients with active infection.

Mediastinal Syndromes of Histoplasmosis Mediastinal adenitis, mediastinal granuloma, and fibrosing mediastinitis are three mediastinal disorders which may complicate histoplasmosis.

Mediastinal Adenitis Mediastinal lymph node involvement is present in most cases of acute and subacute pulmonary histoplasmosis.[80] Although usually asymptomatic, chest pain is the most common manifestation. Rarely, mediastinal lymph nodes can impinge upon the airways, esophagus, or superior vena cava, causing obstructive symptoms. Airway obstruction is more likely in children because their airways are less rigid.

Mediastinal Granuloma Histopathology of mediastinal granulomas shows a necrotic central core, often containing yeast surrounded by caseating and noncaseating granuloma,[80] fibrous tissue, and a thin-walled (<5 mm) capsule. The fibrosis is less exuberant than in fibrosing mediastinitis and does not invade adjacent structures. Symptoms are usually caused by compression of the superior vena cava, esophagus, or airways, and in some cases the nodes liquefy and drain into adjacent structures.[96,97] Disruption of the capsule, either spontaneous or caused by surgery, may create fistulae to the airways, pericardium, skin, or esophagus. Esophageal involvement may result in diverticulum formation.

Mediastinal Fibrosis Mediastinal fibrosis represents an exuberant scarring reaction to mediastinal histoplasmosis.[98,99] The superior vena cava is most commonly involved, but fibrosis also may occlude airways, pulmonary arteries or veins, or the esophagus, and invade the thoracic duct, recurrent laryngeal nerve, or heart in rare cases. Chest radiographs show subcarinal or superior mediastinal widening, while CT scans reveal fibrotic restriction and invasion of mediastinal structures and calcification of lymph nodes. Recurrent postobstructive pneumonias, especially of the right middle lobe, are common. Serious hemoptysis may result from lung or airway damage and vascular compromise. Fibrosing mediastinitis progresses to respiratory failure and death in up to one-third of the patients, especially if the process is bilateral and involves major vessels and airways.[100,101]

Other Inflammatory Syndromes

Inflammatory syndromes complicating histoplasmosis include rheumatologic syndromes and pericarditis.

Rheumatologic Syndromes Patients with subacute histoplasmosis may experience arthritis or arthralgia accompanied by erythema nodosum,[102] a manifestation often misdiagnosed as sarcoidosis.[103] Chest radiographs usually show mediastinal lymphadenopathy and focal pulmonary infiltrates but may also be normal. These findings represent a systemic inflammatory response rather than disseminated infection, and are managed by anti-inflammatory treatment, not antifungal therapy. The illness may recur within weeks to months after treatment is stopped.[104,105]

Pericarditis Pericarditis is another inflammatory complication of primary histoplasmosis, occurring in less than 10% of cases.[106,107] Findings include chest pain, pericardial friction rub, and occasionally, signs of pericardial tamponade. Chest radiographs usually show mediastinal lymphadenopathy and increase in the cardiac silhouette, while CT scan and echocardiogram may show pericardial effusion. These patients respond to anti-inflammatory treatment but may require drainage of the pericardial fluid for the management of tamponade. Development of constrictive physiology is rare; the reasons for this are unclear but could be because the pericardial inflammation is an autoimmune reactive process, rather than a result of direct fungal invasion of the pericardium, and tends to resolve with or without anti-inflammatory treatment.[107]

Progressive Disseminated Histoplasmosis

PDH occurs in about 1 in 2000 cases, usually in patients who are immunosuppressed or at the extremes of age. HIV/AIDS,[108,109] solid-organ transplantation,[60] and treatment with TNF-α inhibitors[61,63] are common predisposing conditions.[110] In organ transplant recipients, PDH develops during the first year after transplant in 34% of cases[60] but may occur up to 10 years after transplantation. Therefore, any signs of disseminated disease should be thoroughly investigated throughout the course of immunosuppression, especially in persons living in endemic areas or those who have new high-risk epidemiologic exposures.

Fever, weight loss, cough and dyspnea are the most common manifestations in PDH.[108,111] Examination reveals hepatomegaly or splenomegaly in about half of cases and lymphadenopathy in a third of cases. A syndrome resembling sepsis may be seen in cases with severe immunosuppression, cases in which corticosteroids are given for presumed inflammatory or autoimmune disease, or in which diagnosis is delayed. Meningitis or focal brain lesions occur in about 5% to 10% of cases.[112,113] Other common sites of dissemination include the oral mucosa, gastrointestinal tract,[114] skin, and adrenal glands in 5% to 10% of cases. Chest roentgenograms are abnormal in 70% of patients, usually showing diffuse interstitial or reticulonodular infiltrates, and less often, a miliary pattern.[111,115]

In patients who experience improvement in immune function during treatment for histoplasmosis, an immune reconstitution syndrome has been reported with a significant degree of morbidity.[61,116–118] Manifestations include respiratory failure, elevation of hepatic enzymes, hepatic or splenic abscesses, lymphadenitis, arthritis, uveitis, and intestinal obstruction in the context of effective control of the infection, decreasing antigen levels, and negative fungal cultures.[61,116–118]

Diagnosis

Diagnostic modalities for histoplasmosis are well developed and validated.[119,120] Histopathology, cytopathology, and antigen detection are the most useful modalities for rapid diagnosis in patients with moderate to severe acute pulmonary histoplasmosis and PDH (Table 133-5).[84,121] Culture results may not be available for up to 1 month due to the prolonged incubation required for growth, limiting utility in this setting. Although less useful overall for acute disease, serology may form the basis of diagnosis for subacute and chronic disease.[121–123] Chronic pulmonary histoplasmosis can also be diagnosed using culture of respiratory secretions, although serology, antigen testing and pathology are also useful.[91,92]

Antigen Detection

Detection of antigen in the body fluids offers a valuable approach to rapid and accurate diagnosis of patients with PDH and acute pulmonary histoplasmosis, providing results within 24 to 48 h.[121] Antigen can be detected in the urine of more than 90% of patients with PDH and 80% with acute diffuse pulmonary disease.[84,121] Sensitivity is improved by testing both serum and urine.[84] Antigen detection is less sensitive in subacute pulmonary histoplasmosis.[121] Detection of antigen in BAL fluid may improve the sensitivity for the diagnosis of pulmonary histoplasmosis.[124] Antigen may be found in the CSF in 50% of patients with *Histoplasma* meningitis.[112,113] Positive

TABLE 133-5 Sensitivity of Various Diagnostics in Different Histoplasmosis Syndromes

	Antigen	Antibody	Pathology	Culture
Acute pulmonary	83%	64%	20%	42%
Subacute pulmonary	30%	95%	42%	54%
Chronic pulmonary	88%	83%	75%	67%
Progressive disseminated	92%	75%	76%	74%
Mediastinal	5%	54%	44%	5%

results caused by cross-reacting antigens occur in patients with African histoplasmosis, blastomycosis, paracoccidioidomycosis, and Talaromyces *marneffei* infection.[121] Antigen levels correlate well with disease severity,[121] and trends can be used to follow disease response to antifungal therapy as they decline during treatment and increase with relapse, providing an effective tool for monitoring therapy at regular intervals (perhaps biweekly for the first month then every 1 to 2 months thereafter until negative or stable).[125–127]

Histopathology and Cytopathology

Fungal staining permits rapid diagnosis but has a lower sensitivity than antigen detection.[121] The highest yield is from bone marrow specimens. Fungal stain of BAL is positive in 70% of cases of diffuse pulmonary histoplasmosis in patients with AIDS with PDH. The sensitivity of fungal stain of sputum or BAL in patients with other types of pulmonary histoplasmosis has not been reported but appears to be low. Yeast may be seen in peripheral blood smears in patients with severe PDH. *Pneumocystis jirovecii, Candida glabrata, Blastomyces dermatitidis, C. neoformans, Toxoplasma gondii,* and *T marneffei* may be misidentified by morphology as *H. capsulatum.*

Serologic Tests

Antibodies to *H. capsulatum* measured by immunodiffusion (ID) or complement fixation (CF) develop in most patients.[120,128] Antibodies may require up to 6 weeks to become detectable following exposure.[129] In acute pulmonary histoplasmosis, antibodies can be detected in about 15% of cases during the first 2 weeks of infection, increasing to about 75% by the sixth week.[129] Outside periods of outbreaks, the background positivity for histoplasma serology in the general population in highly endemic areas is <5%, making a positive test clinically significant even in endemic settings.[123] Patients with asymptomatic or mild infection[130] and those who are receiving immunosuppressive medications following solid-organ transplantation[60,121] may not mount an antibody response. Antibody responses do not appear to be impaired by treatment with TNF inhibitors[61,63,121] and are only slightly impaired in patients with AIDS.[109,121]

Serology is most useful in patients with subacute manifestations of histoplasmosis (pulmonary, rheumatologic, pericardial, and mediastinal syndromes) and chronic pulmonary infection and is positive in 90% of such cases.[121] Sensitivity is higher, while specificity is lower using complement fixation, compared to immunodiffusion, methods. Complement fixation titers greater than or equal to 1:32 are more suggestive of active infection, but titers of 1:8 to 1:16 should not be disregarded. Cross-reactions occur in patients with other fungal diseases. Also, antibodies persisting following prior histoplasmosis may cause confusion in patients with other lung diseases. The newer enzyme immune assay (EIA)-based antibody test with IgG and IgM detection appears to offer higher sensitivity and specificity than the ID and CF in patients with acute pulmonary histoplasmosis. Furthermore, combining antigen and EIA antibody testing increases the sensitivity for diagnosis of acute pulmonary histoplasmosis.[122]

Fungal Cultures

While fungal cultures provide definitive proof for histoplasmosis, they are limited by low sensitivity in self-limited infections and delayed growth (2–4 weeks). Cultures are most sensitive in patients with chronic pulmonary histoplasmosis and PDH.[121] Sputum production is rare in patients with acute subacute pulmonary histoplasmosis, but organisms can be cultured from BAL or other bronchoscopy specimens. In chronic pulmonary histoplasmosis patients commonly expectorate sputum, and organisms can be found in sputum or bronchoscopy specimens in 60% to 85% of cases.[92,121,124] Multiple specimens must be cultured to achieve the highest yield. In PDH, the highest yield is from bone marrow or blood, with positive cultures in more than 75% of cases, and in BAL of patients with pulmonary infiltrates.[121] Cultures are usually negative in pulmonary nodules and mediastinal nodes representing subacute or old healed lesions, despite demonstration of yeast by histopathology.

Molecular Methods

Several studies report diagnosis of histoplasmosis using novel molecular methods in blood, tissues, or body fluids.[20,131] While specificity of the various platforms tend to be very high, sensitivity varies significantly among methods and specimen types.[120] Many improvements have been made over the last two decades with amplification target selection and detection methods, resulting in improved yields.[120] Most studies are limited by a small number of samples and subjects. Further systematic testing at a larger scale is needed to standardize the molecular diagnosis of histoplasmosis.

■ Exclusion of Histoplasmosis in Workup of Patients with Community-Acquired Pneumonia and Suspected Sarcoidosis

Other conditions to be distinguished from histoplasmosis include community-acquired pneumonia and sarcoidosis.

Community-acquired Pneumonia

Histoplasmosis is always community-acquired and is often initially misdiagnosed as other agents of community-acquired pneumonia.[71,132] Failure to suspect and correctly diagnose histoplasmosis may result in errors in patient care, which can lead to improper therapy, unnecessary morbidity, or even death, and higher cost for diagnosis and management. Workup for histoplasmosis should be considered in patients from endemic areas with exposure history, if other causes cannot be established, or if empiric antibiotics do not result in prompt clinical improvement, remembering that histoplasmosis can be prevalent in many areas outside known endemic regions.

Sarcoidosis

Considering the similarity between the two conditions, and the risk for progression of histoplasmosis during immunosuppression for presumed sarcoidosis, active histoplasmosis must be excluded before potent immunosuppressant therapy is initiated.[95,133] If immunosuppressive therapy is initiated in patients with clinical and laboratory findings suggestive of histoplasmosis, the patient should be followed closely for evidence of progression of histoplasmosis. Also, if patients initially respond to immunosuppressive treatment, but later relapse, testing for histoplasmosis should be repeated.

■ Treatment

Most infections (90%) are asymptomatic or clinically self-limited, requiring no therapy. Additionally, treatment has only been well studied in PDH and chronic pulmonary histoplasmosis, precluding assessment of effectiveness in the other syndromes. While treatment in cases of acute pulmonary histoplasmosis appears to be effective, studies showing that therapy hastens response or reduces morbidity have not been conducted. Antifungal therapy for the subacute pulmonary, inflammatory, and mediastinal syndromes is rarely indicated and probably has no effect on the course of the illness, as the pathogenesis appears to involve the inflammatory response and/or mass effects of the enlarged nodes rather than progressive infection.[80]

Comprehensive reviews and treatment guidelines have been published and should serve as reference for indications for the treatment, selection of antifungal agents, duration of therapy, and testing to monitor response.[80,134,135] An earlier Infectious Diseases Society

TABLE 133-6 Treatment Recommendations for Histoplasmosis Syndromes

Syndrome	Recommendation
Acute pulmonary—moderately severe or severe	Liposomal amphotericin B 3.0 mg/kg/d or amphotericin B lipid complex 5.0 mg/kg/d or amphotericin B deoxycholate 0.7–1.0 mg/kg/d for 1–2 weeks followed by itraconazole 200 mg twice daily for a total of 12 weeks Methylprednisolone, 0.5–1.0 mg/kg/d IV for 1–2 weeks
Acute pulmonary—mild to moderate	Symptoms <4 weeks: none Symptoms >4 weeks: itraconazole 200 mg once or twice daily for 6–12 weeks
Chronic cavitary pulmonary	Itraconazole 200 mg once or twice daily for at least 12 months
Progressive disseminated—moderately severe/severe	Liposomal amphotericin B 3.0 mg/kg/d, or amphotericin B lipid complex 5.0 mg/kg/d, or amphotericin B deoxycholate 0.7–1.0 mg/kg/d for 1–2 weeks, then itraconazole 200 mg twice daily for at least 12 months
Progressive disseminated—mild to moderate	Itraconazole 200 mg twice daily for at least 12 months

of America guideline summarized prior studies evaluating therapy for histoplasmosis.[136]

Acute Pulmonary Histoplasmosis

Patients with symptomatic acute pulmonary histoplasmosis manifested by diffuse infiltrates following heavy exposure appear to benefit from antifungal therapy (Table 133-6).[86,137] Adjunctive therapy with corticosteroids may hasten recovery in such patients. Lipid formulations of amphotericin B are preferred as initial therapy in patients with moderate to severe disease because of improved efficacy compared to azole-based therapy and decreased nephrotoxicity compared with amphotericin B deoxycholate. Moreover, improved survival has been reported with liposomal amphotericin B compared with conventional formulations in patients with AIDS and PDH.[138] Itraconazole is recommended in patients with milder disease and as step-down therapy following response to amphotericin B. A 6- to 12-week course is recommended in the absence of PDH, which should be excluded.

Subacute Pulmonary Histoplasmosis

Patients with subacute pulmonary histoplasmosis usually recover without treatment; there have been no studies to determine if treatment alters the course or prevents complications. Nevertheless, treatment is reasonable in patients who show no improvement of symptoms after a month of observation. Oral therapy with itraconazole for 6 to 12 weeks is appropriate.

Chronic Pulmonary Histoplasmosis

Without antifungal therapy, chronic pulmonary histoplasmosis can progress leading to further lung damage and significant morbidity.[2] Treatment improves survival, reduces symptoms, promotes radiographic healing, and eradicates *H. capsulatum* from the sputum. Most patients with chronic pulmonary histoplasmosis can be managed without hospitalization and respond well to treatment with itraconazole for 12 to 24 months. Amphotericin B in conventional or lipid formulations is recommended for initial therapy in patients with more severe respiratory insufficiency to achieve a more rapid clinical response.

Progressive Disseminated Histoplasmosis (PDH)

Treatment is indicated in all patients with PDH. The mortality of untreated disseminated histoplasmosis is greater than or equal to 80% but can be reduced to less than 10% with timely and effective therapy.[60,63,109,138] Lipid formulations of amphotericin B are preferred as initial therapy in patients with moderate to severe disease because of improved efficacy and decrease nephrotoxicity. Induction therapy with amphotericin is given for 1 to 2 weeks, followed by step-down to oral itraconazole after clinical and radiographic response. In cases of patients with milder disease, itraconazole can be effective. A total duration of 12 to 24 months is recommended in most cases. In patients who cannot tolerate prolonged courses of itraconazole, other azoles, including fluconazole, voriconazole, posaconazole, or isavuconazole, can be used (see “Alternative Antifungal Agents,” below).

Mediastinal Adenitis and Granuloma

Patients with obstructive symptoms or fistula caused by mediastinal granuloma and adenitis should be treated, but whether treatment alters the outcome remains unknown.[80] Itraconazole for 6 to 12 weeks is recommended, after which imaging studies should be repeated to assess response. If the enlarged nodes show reduction in size, therapy might be continued for a total of 3 to 6 months. Surgery should be considered if symptoms persist and are sufficiently bothersome.[139] Antifungal treatment or resection of enlarged mediastinal lymph nodes to prevent fibrosing mediastinitis is not indicated since progression of enlarged mediastinal nodes to fibrosing mediastinitis has not been documented.[98,140]

Mediastinal Fibrosis

Antifungal treatment is not thought to improve the outcome of mediastinal fibrosis, but therapy with itraconazole 6 to 12 weeks is commonly tried and is reasonable, considering the seriousness of this complication. Occasionally, patients benefit from the placement of stents in pulmonary vessels or the superior vena cava.[141] Stenting of the airways is not recommended because of the risk for growth of inflammatory tissue causing obstruction of the stent.[80] Surgery is associated with a high mortality and limited efficacy and should generally be discouraged. In patients with no other options, care should be taken to select a surgeon experienced with this rare manifestation of histoplasmosis.

Broncholithiasis

Surgical therapy is required for patients with significant hemoptysis or recurrent pneumonia and for repair of fistulae. Antifungal therapy is not expected to reduce the symptoms since active infection is uncommon in such cases.

Inflammatory Syndromes

Rheumatologic syndromes and pericarditis are noninfectious, inflammatory manifestations and respond to anti-inflammatory therapy.

Histoplasmosis-related pericarditis is treated similarly to pericarditis from other inflammatory causes, usually with nonsteroidal anti-inflammatory drugs and colchicine. Steroids should be avoided, if possible, as they are associated with an increased risk of recurrent pericarditis.[142] Antifungal therapy is not indicated unless there is evidence of yeast in bone, joint, or pericardial tissues, or if corticosteroids are used for treatment of the inflammatory syndrome.

Selection of Antifungal Agents

Amphotericin B acts more rapidly than triazole antifungal agents and is recommended for moderate or severe cases which require hospitalization and women who are pregnant.[135] Liposomal amphotericin B was shown to be superior to the amphotericin B deoxycholate formulation in patients with AIDS with histoplasmosis, with improved overall response and decreased mortality and side effects.[138] Patients who were treated with liposomal amphotericin B experienced a faster resolution of fever, higher overall response, better survival, and lower toxicity.[138] Liposomal amphotericin B, 3.0 mg/kg/d, or amphotericin B lipid complex, 5.0 mg/kg/d, is recommended for patients with moderate to severe PDH. Treatment can be changed to itraconazole after the patient improves, usually in 3 to 14 days.

Itraconazole is highly effective in most mild to moderate cases of PDH and in chronic pulmonary histoplasmosis.[60,63,109] Itraconazole capsules require an acidic gastric environment for solubilization and should be given with food or carbonated beverages. Medications that reduce gastric acidity should be avoided. Itraconazole solution is a good alternative in patients who require gastric acid suppression or who have low blood itraconazole levels while taking the capsule formulation. Itraconazole blood levels should be measured after 2 to 3 weeks of therapy with a sample obtained just before a dose, aiming for a trough concentration between 1 and 10 μg/mL when measured by high-pressure liquid chromatography (HPLC).[143] Levels measured by bioassay should generally be about two times higher than HPLC, with a the target concentration between 3 and 10 μg/mL. The solution formulation achieves concentrations that are ~30% higher than the capsule formulation.

Drug interactions can be common with itraconazole. Hepatic enzyme inducers, such as rifampin, reduce itraconazole concentrations and should be avoided. Itraconazole also inhibits intestinal and hepatic cytochrome P450 3A4, causing accumulation of several drugs and increasing associated toxicities.[144] As the list of contraindicated medications continues to evolve, physicians and pharmacists should closely review potential drug interactions before starting itraconazole and when new medications are added to the regimen. Furthermore, itraconazole is eliminated by hepatic metabolism. Itraconazole may also cause congestive heart failure and should be avoided in patients with heart disease unless the benefit outweighs the risk.[145] If itraconazole is used in patients with cardiac disease, careful follow-up for the development of heart failure is essential, and if heart failure develops, itraconazole should be stopped.

Alternative Antifungal Agents

Fluconazole, voriconazole and posaconazole are active in vitro against *H. capsulatum.*[146] Fluconazole is less active in vitro than itraconazole for histoplasmosis. Isolates from patients who failed fluconazole exhibited at least a fourfold reduction in susceptibility to fluconazole in more than two-thirds of cases.[146] In patients with AIDS and PDH treated with fluconazole, 800 mg/day for 12 weeks, followed by 400 mg/day indefinitely, failure occurred in up to one-half of patients within 6 months.[147,148]

Voriconazole MICs are higher compared to other azoles and may further increase after fluconazole exposure, leading to some concern regarding the use of voriconazole for treatment of histoplasmosis.[146] A recent study comparing outcomes of treatment for histoplasmosis with itraconazole or voriconazole reported higher mortality during the first 42 days in those treated with voriconazole.[149]

On the other hand, posaconazole was effective in an experimental model of histoplasmosis[150] and as a salvage treatment in a small series of patients with disseminated histoplasmosis.[151] In addition, extended-release formulation of posaconazole afford more reliable serum levels and are associated with a better side effect profile than voriconazole.

Isavuconazole exhibits in vitro activity against *H. capsulatum* and has been successfully used for treatment of cases of pulmonary and extrapulmonary histoplasmosis, but data remain limited.[152–154]

Echinocandins are not active in vitro or effective in murine models and have not been well studied in patients with histoplasmosis.[155] Taken together, these data suggest that posaconazole may be the best alternative if itraconazole cannot be used.

Duration of Therapy and Special Populations

Lifelong maintenance therapy was the standard of care in patients with AIDS complicated by PDH before the advent of ART. With ART, maintenance therapy can be discontinued in patients who (1) have received at least 1 year of itraconazole, (2) have antigen levels less than 2 ng/mL in urine and serum, and (3) have a CD4 count greater than 150 cells/mm^3.[109,135,156] Patients must be carefully monitored for relapse and continued response to ART. Resumption of antifungal therapy is recommended if the CD4 count falls below 100 cells/mm^3 or if antigen levels in urine or serum increase, providing evidence of relapse. In patients who develop histoplasmosis while on anti-TNF therapy, after 12 months of effective antifungal therapy with documented clearance of the infections, anti-TNF agents can be safely resumed with close clinical and microbiologic monitoring with serial antigen testing at monthly intervals.[61,63] For recipients of solid organ transplantation, immunosuppression should be reduced concomitantly with antifungal treatment to improve treatment response and reduce likelihood of relapse. Treatment should be continued for at least 12 months and until antigen levels are less than or equal to 2 ng/mL, since relapse is more likely if levels are greater than 2 ng/mL at time of treatment cessation. After stopping treatment, antigen levels should be monitored frequently (e.g., monthly) for at least 6 months.[157] Monitoring of antigen levels can be performed on both urine and serum, although serum levels have been shown to correlate more closely with treatment response.[125,127]

■ Prevention

Patients at high risk for dissemination should avoid activities that expose them to *H. capsulatum*, such as caving or remodeling old buildings inhabited by bats or birds. Hand-washing reduces the risk for acute histoplasmosis among persons exposed while crawling in a bat-inhabited cave, while use of loose-fitting paper masks does not. A placebo-controlled study using itraconazole, 200 mg daily, in persons with AIDS demonstrated reduction in the incidence of histoplasmosis.[158] However, since the introduction of ART, the incidence of these infections has declined and is too low to justify prophylaxis. Prophylaxis may be reasonable in patients with HIV/AIDS and a CD4 count of less than 150 cells/mm^3 living in areas where the combined incidence of systemic fungal infections exceeds 10 cases per 100 patient-years.[135] Screening for histoplasmosis is not recommended prior to transplantation, as the risk of reactivation post-transplant is extremely low.[157]

BLASTOMYCOSIS

B. dermatitidis, the agent of blastomycosis, is the least common and the least well-understood endemic mycosis within the United States. Although many clinical and radiographic features overlap with those of histoplasmosis and coccidioidomycosis, blastomycosis exhibits certain distinctive characteristics. These include a greater predilection for immunocompetent hosts, a tendency for pulmonary consolidations to appear mass-like, the frequent absence of mediastinal and hilar lymphadenopathy, and a greater proclivity for extrapulmonary dissemination to the skin. On microscopy, *B. dermatitidis* also differs from other North American dimorphic fungi both in terms of the characteristics of individual yeast cells as well as the histopathologic inflammatory reaction engendered. Although previously thought to be essentially restricted to the United States and Canada, cases of blastomycosis have also been reported in Africa and Southeast Asia. Moreover, *Blastomyces* quasispecies including *B. helicus*, *B. percursus*, and *B. emzantsi* are being increasingly recognized as causes of human disease in North America and Africa.

Epidemiology

Although *B. dermatitidis* has been isolated from soil enriched with animal excreta and rotting wood, particularly in areas proximate to waterways and bodies of water, the exact environmental reservoir of *B. dermatitidis* is unknown, hindering the epidemiologic characterization of blastomycosis. Additionally, *B. dermatitidis* serologic testing is characterized by poor sensitivity and specificity, lessening the utility of serosurveillance studies in characterizing the geographic extent of this fungus.[159] Furthermore, the incidence and prevalence of blastomycosis may be underestimated since many regions in the United States and Canada do not mandate public health reporting of cases of blastomycosis. Zoonotic cases of blastomycosis, particularly among dogs, often exceed and precede human cases. As such, these have served as surrogates for changes in the epidemiology of human disease and an early indicator of increases in incidence.[160]

The areas of highest endemicity for blastomycosis are located within the North American continent in states bordering the Mississippi, Ohio, and St. Lawrence River valleys, the south central and northern Midwestern states, and the Canadian provinces along the Great Lakes (Fig. 133-1). The Kenora region of northwestern Ontario in Canada has the highest reported incidence of blastomycosis in the world.[161] In the United States, the highest-incidence states are Louisiana, Arkansas, Mississippi, Tennessee, North and South Carolina, Kentucky, Missouri, West Virginia, Illinois, and Wisconsin.[1] The incidence of blastomycosis cases has steadily increased over recent years across endemic areas of Canada and the United States, as well as in regions outside the traditional geographic confines of endemicity. Following a recent rise in the number of cases in areas along the St. Lawrence River in Upstate New York, the State newly designated blastomycosis an emerging disease that is reportable to local health departments.[162] Cases of blastomycosis in persons with no history of out-of-state travel have been reported in Colorado, Oregon, Nebraska, and Florida, suggesting local acquisition in areas not known to be endemic.[163] In Canada, several cases of blastomycosis were reported in the traditionally non-endemic area of southern Saskatchewan in patients who had never traveled to endemic areas, suggesting a broader region of endemicity than previously known.[164] Outside of North America, the endemicity of blastomycosis is still less well understood, but most cases are reported from Africa, with most coming from Tunisia, South Africa, and Zimbabwe.[1] Although cases have been reported from the Asia–Pacific region, including India, it remains unclear whether these represent true local acquisition.[1]

Risk factors for blastomycosis include construction, forestry, and other occupational exposures to disrupted soil or decaying vegetation.[165] Male sex and certain races, including Black and Canadian Aboriginal races, are associated with an increased risk for blastomycosis, thought to be mainly a function of increased occupational and recreational exposures.[166] An increased genetic predilection for blastomycosis has been suggested for Asian residents of Hmong ethnicity after this group was found to be 12 times more likely than non-Asians to develop clinical blastomycosis in a Wisconsin outbreak in 2009.[167] Both limited and disseminated disease can occur in immunocompetent patients, usually as a result of exposure to large fungal inocula, but individuals with defects of cellular immunity are at increased risk for disseminated and severe disease. These include recipients of solid organ and bone marrow transplantation and patients on high-dose corticosteroids and TNF-α blockers.

Blastomyces species other than *B. dermatitidis* are increasingly recognized as causes of human disease. In a study of 20 cases of blastomycosis in South Africa, morphologic, phylogenetic, and whole genome sequencing analyses revealed that all 20 cases belonged to *Blastomyces* species that were closely related to, but distinct from, *B. dermatitidis*, including *B. percursus* and *B. emzantsi.*[168] Notably, disseminated disease to the skin and bones, including sinus track formation in some cases, was more common than isolated pulmonary disease. Additionally, fungi previously designated under the genus *Emmonsia* have been reclassified as *Blastomyces* based on genetic analyses, including *Emmonsia parva* (now *Blastomyces parvus*) and *Emmonsia helica* (now *Blastomyces helicus*). *B. helicus* was reported as a cause of severe pulmonary, systemic, and central nervous system disease, mostly among immunocompromised patients (71%) in the United States and Canada.[169]

Mycology

At body temperature (37°C), *B. dermatitidis* exists as a uniform, moderate-sized yeast (ranging from 8 to 15 μm but sometimes as large as 40 μm) with thick double-refractile walls and broad-based budding (Fig. 133-2). At room temperature (25°C) and when incubated at 30°C ± 2°C in laboratory settings, *B. dermatitidis* uptakes the form of a septated mold with round or piriform conidia at the end of conidiophores. Macroscopically, *B. dermatitidis* colonies are white or off-white with a cottony texture and a reverse that is tan in color. Microscopically, *B. dermatitidis* is distinct from *H. capsulatum* var. *capsulatum* which is much smaller (2–4 μm) and exhibits narrow-based budding, and from *C. posadasii/immitis* which exists as a much larger non-budding, endospore-containing spherule (up to 200 μm). However, several yeast and yeast-like structures can mimic *B. dermatitidis* on histology (Fig. 133-5). Immature C. *posadasii/immitis* spherules may have a similar size and appearance to *B. dermatitidis* yeast and must be distinguished by searching for characteristic mature spherules. When variable in size, *B. dermatitidis* can mimic non-encapsulated strains of *Cryptococcus,* which often exists as a mixture of smaller and larger organisms. *H. capsulatum* var. *duboisii* is a moderately-sized yeast with thick walls similar to *B. dermatitidis* but with narrow-based, hourglass-shaped budding. Finally, *Lacazia loboi*, the etiologic agent of lobomycosis, has thick, double-refractile walls like *B. dermatitidis* but often occurs in linear chains, which is a characteristic and distinguishing feature. Additionally, other rare *Blastomyces* species, including *B. percursus* and *B. helices,* with differing microscopic features must be considered.[168]

Pathogenesis

Infection primarily occurs via the respiratory route, following inhalation of aerosolized conidia from the environment into terminal alveoli of mammalian lungs. Less commonly, direct cutaneous inoculation of conidia can occur after a penetrating injury (such as with a branch contaminated with fungal spores), leading to primary cutaneous blastomycosis. After gaining entry into the human host, *B. dermatitidis* conidia transform into more pathogenic yeast forms under higher body temperature conditions, unless they are phagocytosed and destroyed by neutrophils and alveolar macrophages. In a host who is immunocompromised or when the fungal inoculum is high, the immune system is unable to fully interrupt the cascade of

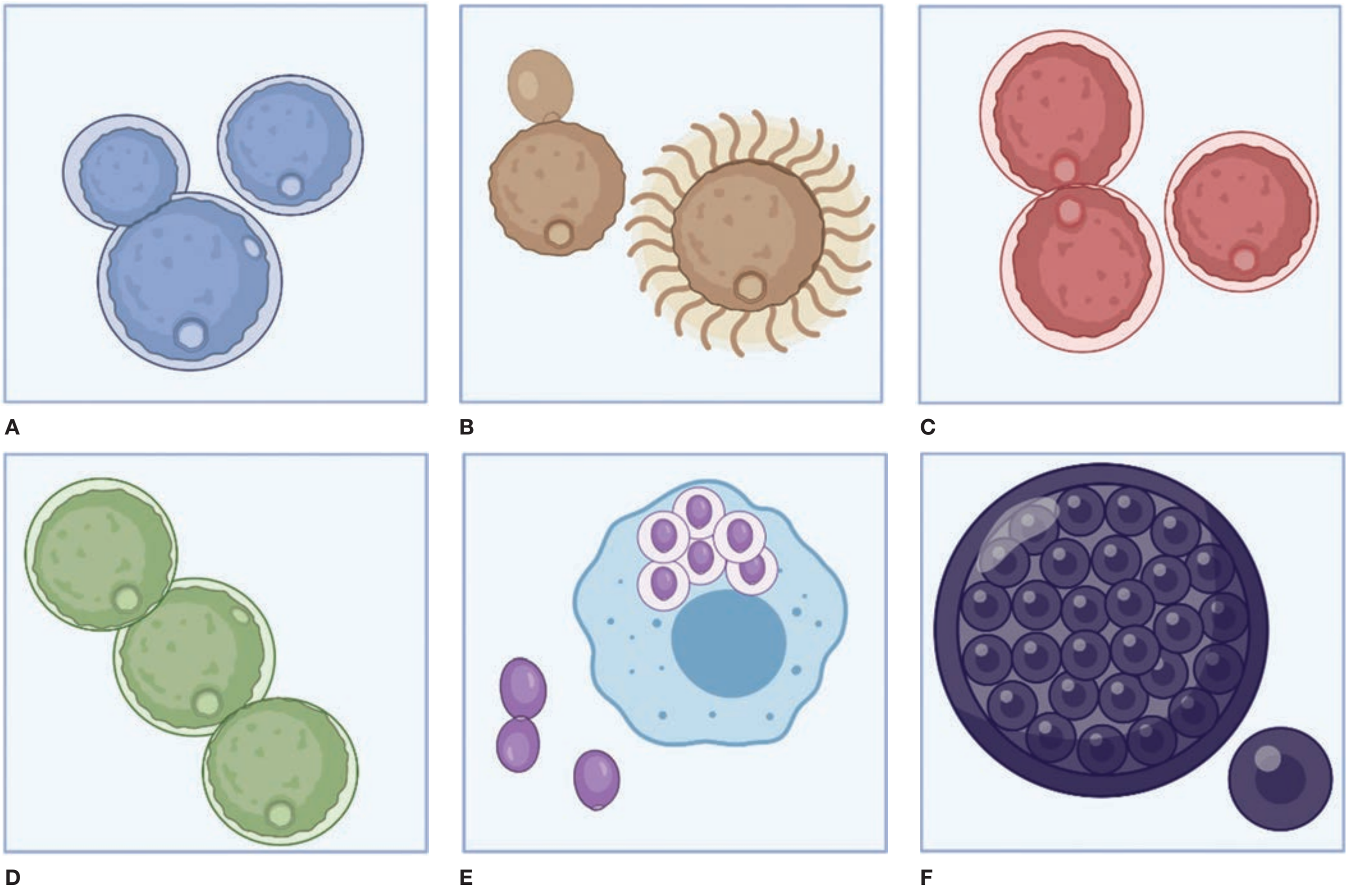

Figure 133-5 Microscopic appearance of *B. dermatitidis* (**A**) and mimics including *C. neoformans/gattii* (**B**), *H. capsulatum* var. *duboisii* (**C**), and *L. loboi* (**D**). Other important endemic fungi are shown including *H. capsulatum* var. *capsulatum* (**E**) and *C. immitis/posadasii* (**F**).

infection, allowing some conidia to evade phagocytosis and progressive infection to develop. *B. dermatitidis* yeast can successfully evade the immune system through impaired neutrophil recruitment, defensin production, macrophage priming, and granuloma formation. Several mechanisms are responsible, including inhibition of Th1 and Th17 cell activation and downregulation of (1–3)-B-D-Glucan, a fungal cell wall component that also functions as a ligand for fungal host–cell pattern recognition receptors.[170] In addition to acting as a virulence factor by decreasing host recognition, low (1–3)-B-D-Glucan cell wall content has implications for diagnostics and treatment by reducing the efficacy of glucan-targeting echinocandin antifungals and association with poor sensitivity of diagnostic assays that detect circulating (1–3)-B-D Glucan.[171]

Pathologically, blastomycosis is characterized by granuloma formation with central microabscesses. This pyogranulomatous response is in contrast to the purely granulomatous response as seen with histoplasmosis or tuberculosis, and to the often-eosinophilic granulomatous response that occurs with coccidioidomycosis. Histologic changes in the skin may resemble those of squamous-cell carcinoma or keratoacanthoma. Calcification is uncommon.

■ Clinical Manifestations

Blastomycosis most often affects the lungs with a spectrum of disease ranging from asymptomatic infection to acute and chronic pneumonia, ARDS, and disseminated disease. A greater proportion of disease is symptomatic with blastomycosis (50%) compared to histoplasmosis (10%) and coccidioidomycosis (40%).[71,172] The incubation period is a median of 45 days, with a range of 21 to 106 days; shorter incubation periods are seen in immunocompromised patients or in high-inoculum exposures.[159]

Acute and Chronic Pneumonia

Two distinct syndromes of pneumonia occur in patients exposed to *B. dermatitidis*: acute pulmonary blastomycosis with or without ARDS and chronic pulmonary blastomycosis.

Acute pulmonary blastomycosis is characterized by the abrupt onset of respiratory symptoms including productive or dry cough, dyspnea, and pleuritic chest pain and constitutional symptoms including fevers, chills, night sweats, weight loss, fatigue, and malaise. The presentation can be mistaken for bacterial community-acquired pneumonia, leading to inappropriate use of antibiotics and delays in diagnosis. The correct diagnosis is often suspected only after symptoms fail to improve with antibacterial therapy or in the context of a blastomycosis outbreaks in endemic areas. In a multicenter retrospective study of pulmonary blastomycosis cases in Minnesota and Wisconsin, the median number of visits required to make a diagnosis was 2 (interquartile range, 1–4), encompassing a median of 23 days (interquartile range, 8–36 days); the median number of prior antibiotic courses was 2.5 (interquartile range, 1.5–4.5).[173] Almost half of patients required hospitalization, including 14% in the intensive care unit. The most common radiographic findings in acute pulmonary blastomycosis include uni- or multilobar consolidation and nodular infiltrates[174,175] (Fig. 133-6). Other patterns include cavitation, focal or diffuse ground-glass opacities, and unilateral or bilateral pleural effusions.[176] Miliary nodules and interstitial infiltrates are often seen in severe disease and ARDS. Unlike histoplasmosis (>60%) and coccidioidomycosis (40%), mediastinal and hilar lymphadenopathies are much less common with pulmonary blastomycosis (10%).[71]

Chronic pulmonary blastomycosis is more common in sporadic cases than in an outbreak setting. It is characterized by the insidious

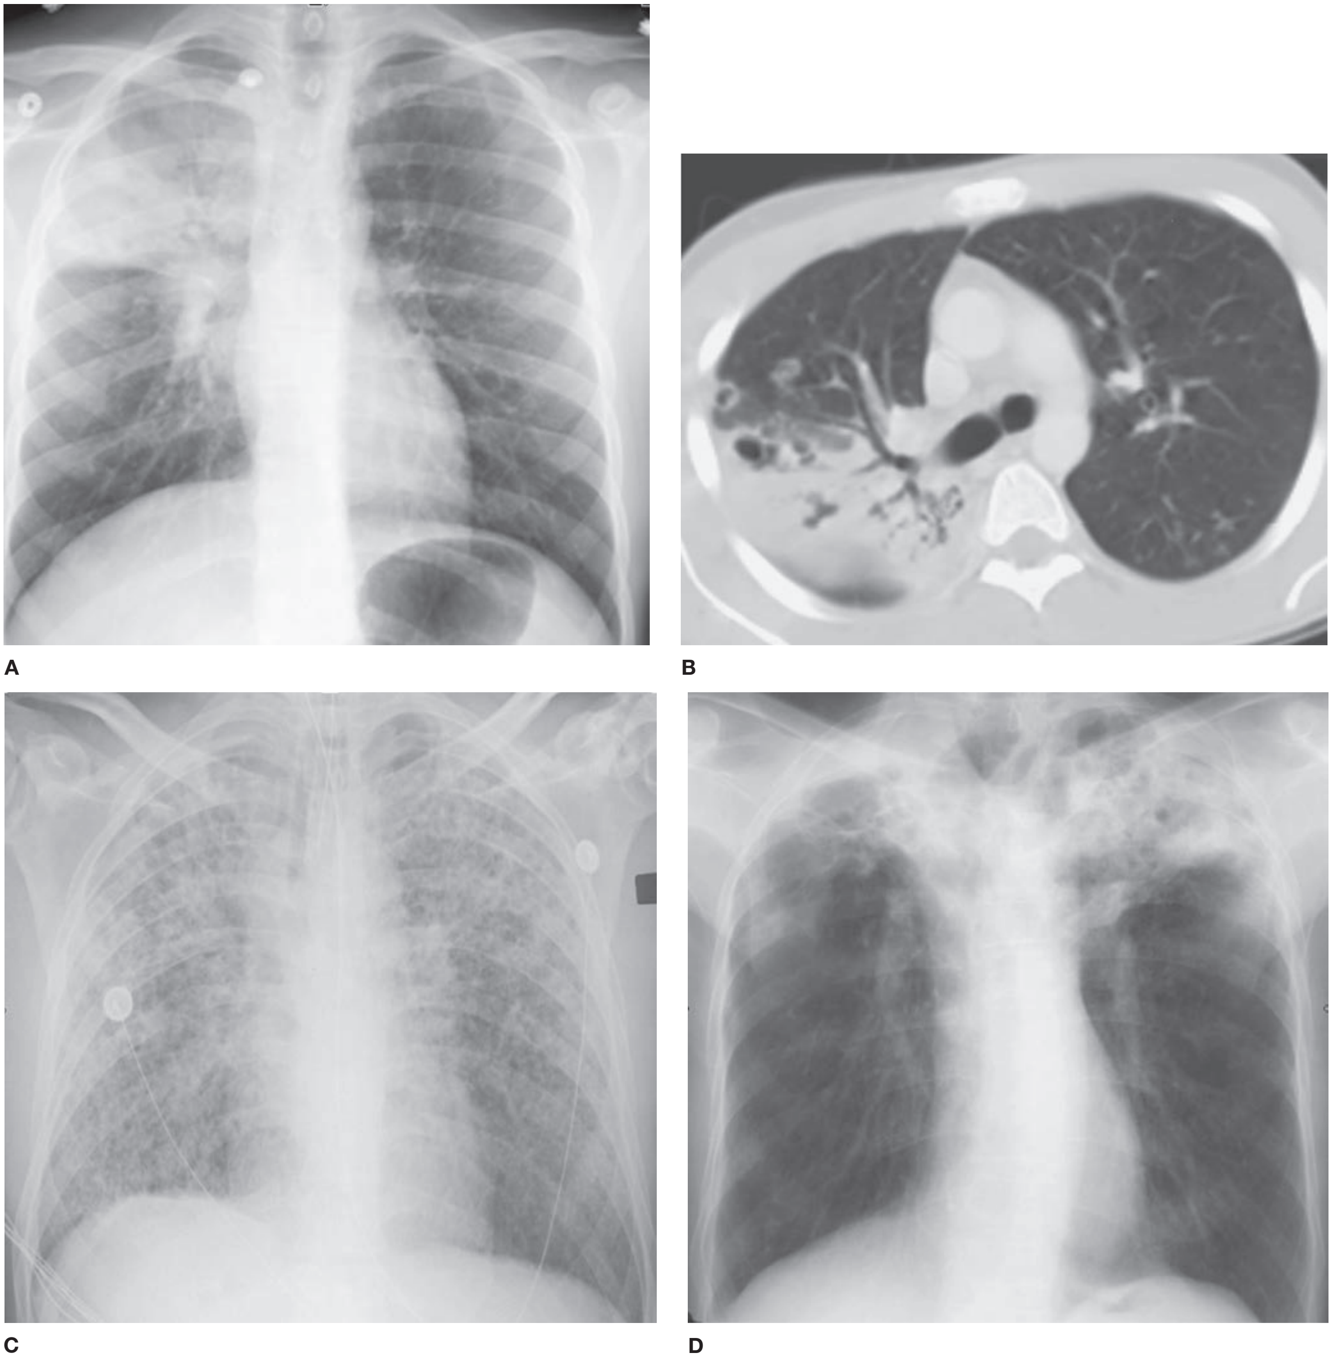

Figure 133-6 **A.** Chest radiograph of infiltrate resembling bacterial pneumonia in acute blastomycosis. **B.** Computed tomography scan showing lobar infiltrate in blastomycosis. **C.** Chest radiograph of diffuse infiltrates associated with acute respiratory distress syndrome in blastomycosis. **D.** Chest radiograph of cavitary blastomycosis.

onset of respiratory and constitutional complaints lasting weeks to months, mimicking other chronic endemic fungal pneumonias, tuberculosis, sarcoidosis, and lung cancer. The illness tends to progress if left untreated. Chronic pulmonary blastomycosis is as or more common than the acute form. In two studies from Tennessee and Arkansas, approximately 60% of patients presented with chronic pneumonia.[177,178] On imaging, consolidations, nodules, and fibrocavitary disease can be seen. Consolidations often appear mass-like, mimicking lung cancer, but PET scanning using fluorodeoxyglucose-F18 is not sensitive enough to distinguish these two conditions.[179,180] Fibrocavitary disease is less common than in histoplasmosis and coccidioidomycosis and is seen in $<10\%$ of cases. As with the acute form, lymphadenopathy is uncommon.

Acute Respiratory Distress Syndrome

Acute pulmonary blastomycosis may be complicated by the development of ARDS, which is characterized by bilateral pulmonary infiltrates and hypoxic respiratory failure requiring mechanical ventilation, without or without circulatory shock.[181] Progression to ARDS may occur and is associated with high mortality of $>50\%$, partly from delayed disease recognition and institution of appropriate antifungal therapy.[182] In one retrospective study of 114 patients with blastomycosis, 15% of patients developed ARDS; mortality in this group was 47%.

Lung pathology in ARDS is characterized by dense alveolar consolidation, microabscesses, hyaline membranes, and abundant yeasts. Although ARDS is often seen in immunocompromised patients, such as individuals with HIV/AIDS or diabetes, transplant recipients, and patients receiving treatment with TNF inhibitors, immunocompetent patients also may be affected.[182–185] In the series of cases of blastomycosis series noted above, only 50% of patients with ARDS were immunocompromised, highlighting a broad pathogenic potential that extends to normal hosts.[175] Despite appropriate antifungal therapy, the mortality rate of blastomycosis-associated ARDS remains high (47%–89%).[175,178,181,186]

Disseminated and Extrapulmonary Blastomycosis

Extrapulmonary blastomycosis occurs in a substantial number of cases (25%–40%), usually as a result of dissemination from the lungs, although direct cutaneous inoculation can occur.[171,187] Skin lesions are the most common extrapulmonary manifestation, usually occurring after resolution of acute pulmonary disease, or concurrently with chronic pulmonary blastomycosis, often on the face. In one series, 31% of patients with pulmonary blastomycosis had concurrent cutaneous involvement.[175] Skin lesions are most often verrucous or ulcerative, but nodules or pustules can occur. Ulcerative lesions may masquerade as pyoderma gangrenosum.[188] The most common extrapulmonary sites after the skin are the bones and joints (18%), genitourinary track (13%, particularly the prostate), and the central nervous system (CNS, 5%–10%).[189] CNS blastomycosis is most common in immunocompromised patients, especially in those with HIV/AIDS for whom a rate as high as 40% has been reported.[183,190] CNS infection may manifest as acute or chronic meningitis with diffuse leptomeningeal enhancement, or as focal brain lesions. In a multicenter study of 22 cases of CNS blastomycosis, manifestations included epidural abscess (n = 1), meningitis (n = 7), intracranial mass lesions (n = 10), and concomitant mass lesions and meningitis (n = 4). CNS disease is associated with a high mortality rate of ~20%.[191] Immunocompromised patients with extrapulmonary disease are more likely to have relapse after treatment cessation.

■ Diagnosis

Blastomycosis is a protean disease that requires a high index of suspicion. Even in endemic areas, the diagnosis is often delayed. Inquiry must be made about recent acute and more longstanding respiratory and systemic symptoms, as well as possible high-risk exposures through occupational or recreational activity and travel to endemic areas. Symptoms in family members or friends and even in pet dogs may serve as a clue of local outbreaks. An in-depth physical examination looking for signs of respiratory, skin, osteoarticular, and CNS disease must be performed. A definitive diagnosis requires histopathology demonstrating compatible yeast forms and growth on culture, but the detection of *Blastomyces* antigen has proved useful for rapid diagnosis of pulmonary and disseminated blastomycosis (Table 133-7).[192] Increased sensitivity may be achieved by use of several diagnostic methods.[124,159,174,175,193–195]

TABLE 133-7 Diagnostic Studies in Blastomycosis

Test	Sensitivity (%)
Antigen	93
Cytology	50–93
KOH	29–83
Histopathology	85
Culture	66–75
Serology	<50

Culture

The gold standard for diagnosis of blastomycosis requires isolation of *B. dermatitidis* on culture of various specimens including respiratory fluid (sputum, tracheal aspirate, BAL fluid), skin biopsy, and others. The yield of culture from BAL fluid is higher with blastomycosis than with histoplasmosis (92% vs. 50%).[195] A drawback of relying on culture for the diagnosis of blastomycosis is the prolonged incubation time of 1 to 4 weeks required for growth. After isolation of the fungus, a preliminary diagnosis can be done by microscopic examination of hyphal and conidial structures under light microscopy. Historically, culture confirmation was further performed by incubating mold colonies at higher temperature to achieve thermoconversion into yeast. More recently, this time-consuming practice has been replaced by culture confirmation using DNA hybridization probe applied to fungus isolated from culture (see "Molecular Testing," below).

Histopathology and Cytopathology

Direct visualization of *B. dermatitidis* yeast on tissue specimens obtained via biopsy can support a diagnosis for blastomycosis. Histopathologic examination of biopsy specimen is up to 81% sensitive.[175,191] Although yeast can be visualized on standard hematoxylin and eosin staining, detection is improved with the use of special stains including the Gomori methenamine silver and periodic acid–Schiff stains. Mucicarmine and Fontana-Masson stains allow differentiation of *B. dermatitidis* from *C. neoformans* by staining the cryptococcal capsule and cryptococcal melanin, respectively. Similarly, detection of organisms on respiratory or other liquid specimens using cytopathology can provide a rapid diagnosis when positive, although the yield is variable, ranging from 38% to 97%, contingent on specimen quality, stains type, and cytopathologist experience.[175,196] When applied to the same specimen, the combination of culture and cytology increases the sensitivity of testing.[197] A drawback of these approaches is the need for invasive procedures, including bronchoscopy and transbronchial, surgical, or percutaneous biopsy, to obtain specimens.

Antigen Testing

Blastomyces antigen can be detected in multiple body fluids, including urine, serum, BAL, and CSF and provides a rapid, noninvasive, and sensitive method for detection that has vastly improved the ability to diagnose blastomycosis. Antigen testing is overall most sensitive when applied to urine (up to 93%), although the sensitivity is lower in patients with mild and localized disease as compared to those with severe and disseminated disease. Serum and BAL antigen testing sensitivity is 5% to 20% lower than urine. Data for CSF antigen testing are limited, but the test is useful when positive. Importantly, a positive *Blastomyces* antigen cannot differentiate blastomycosis from histoplasmosis due to almost uniform cross-reactivity of antigen testing. Cross-reactivity with other endemic fungi also occurs, including *Paracoccidioides braziliensis* and *Talaromyces marneffei.*[120,131,191,194,198–200] Antigen levels can be followed (usually monthly) as a means of assessing treatment response, as is done with histoplasmosis.[127]

Serology

In contrast with histoplasmosis and coccidioidomycosis, commercially available serology for blastomycosis is not clinically useful due to poor sensitivity and specificity (immunodiffusion sensitivity, 33%–85%; complement fixation sensitivity, 33%–50%).[71] *Blastomyces* serology cross-reacts significantly with *H. capsulatum*. A laboratory-developed enzyme immunoassay targeting the *Blastomyces* A antigen (BAD-1) has been shown to be more sensitive (88%) and specific (99%) with little cross-reactivity with *H. capsulatum* (6%), but it is not yet commercially available.[200]

Molecular Testing

Based on traditionally higher sensitivity and specificity than other methods, nucleic acid–based methods promise to supersede antigen testing for the diagnosis of blastomycosis. However, in real-world practice, molecular methods are not routinely used in the direct detection of blastomycosis because of variable performance and lack of standardization. A laboratory developed real-time PCR assay applied to culture isolates and clinical specimens achieved high sensitivity and specificity and showed no cross-reactivity between *B. dermatitidis* and *H. capsulatum*, confirming the high potential of this methodology.[131] Although not yet widely used for direct specimen detection of *H. capsulatum*, molecular testing is routinely used for identification of cultured isolates in the microbiology laboratory. One such assay is the AccuProbe, which employs a single-stranded DNA probe with a chemiluminescent label complementary to a sequence of *B. dermatitidis* rRNA. Fluorescence produced by labeled DNA:RNA hybrids is subsequently measured by a luminometer to determine whether the signal crosses the threshold for positivity. Culture confirmation can also be done via PCR sequencing in reference laboratories.

■ Treatment

Unlike with histoplasmosis and coccidioidomycosis, consensus guidelines recommend treatment for all patients diagnosed with blastomycosis because of a higher likelihood of symptomatic disease, progression to severe or disseminated disease, and development of chronic blastomycosis if left untreated (Table 133-8).[134,201] In some cases, patients with mild disease restricted to the lungs and without any immunocompromising conditions may be considered for observation and expectant management. However, this requires close and long-term follow-up to ensure that chronic infection has not ensued. Transplacental transmission of blastomycosis has rarely been described. Pregnant women do not appear to be at increased risk for poor outcomes.[196] Treatment of mothers may reduce the risk of transmission to fetus and should employ amphotericin B as the triazoles are contraindicated due to teratogenicity. Although data are scarce, lipid formulations of amphotericin B appear to be safe in pregnancy.[202]

Acute Pulmonary Blastomycosis

For acute pulmonary blastomycosis of mild to moderate severity, oral itraconazole (200 mg three times a day for three days as a loading dose, followed by 200 mg twice a day for maintenance) is recommended for a duration of 6 to 12 months, along with therapeutic drug level monitoring (with a target itraconazole serum level of ≥1.0 mg/mL at 2 weeks after initiation of therapy). Itraconazole has been associated with >90% success rate in this setting.[203] Fluconazole is less effective than itraconazole for blastomycosis. Higher doses of fluconazole (800 mg daily) may be considered as an alternative when itraconazole cannot be tolerated.[201,204]

For severe pulmonary blastomycosis, a lipid formulation of amphotericin B (3–5 mg/kg/d) is recommended for 1 to 2 weeks and until there is clinical improvement. Lipid formulations are associated with lower nephrotoxicity than conventional amphotericin B (0.7–1.0 mg/kg/d). The response rates to amphotericin B in this setting range from 85% to 90%.[205] Adjunctive steroids have been suggested for treatment of severe pulmonary disease with ARDS. There are few data to guide this practice, but in one small study, mortality was lower in patients with blastomycosis-associated ARDS who received corticosteroids than those who did not (2 of 6 patients vs. 6 of 11 patients).[175] Following clinical improvement, intravenous therapy can be stepped down to oral itraconazole for a total of 6 to 12 months.

TABLE 133-8 Treatment Recommendations for Blastomycosis Syndromes

Syndrome	Recommendation
Acute or chronic pulmonary—moderate to severe	Lipid amphotericin B 3.0–5.0 mg/kg/d or deoxycholate amphotericin B 0.7–1.0 mg/kg/d for 1–2 weeks followed by itraconazole 200 mg twice daily for 6–12 months ARDS: Can consider adjunctive methylprednisolone, at around 1.0 mg/kg q6h IV for 1–2 weeks
Acute or chronic pulmonary—mild to moderate	Itraconazole 200 mg twice daily for 6–12 months
Disseminated blastomycosis with CNS involvement	Lipid amphotericin B 5.0 mg/kg/d for 4–6 weeks followed by itraconazole 200 mg twice daily or voriconazole 200–400 mg twice daily for at least 12 months

Chronic Pulmonary Blastomycosis

Chronic pulmonary blastomycosis is often symptomatically mild and is treated with oral itraconazole for at least 6 months and until there is radiographic and clinical improvement.

Extrapulmonary and CNS Blastomycosis

Treatment of extrapulmonary blastomycosis depends on severity and site of dissemination.[201] Mild to moderate disease is treated with itraconazole for 6 to 12 months (12 months for osteoarticular disease), while moderate to severe disease is treated with amphotericin B for 1 to 2 weeks, followed by itraconazole for 12 months. CNS disease always requires an induction phase with amphotericin B of 4 to 6 weeks, prior to stepdown therapy with itraconazole. There are reports of successful use of voriconazole for treatment of CNS blastomycosis, thought to be associated with its ability to achieve higher drug concentrations in CSF and brain tissue than itraconazole. In a retrospective multicenter study of 22 cases of CNS blastomycosis, 8 patients received step-down therapy after induction with amphotericin B, and of these, 7 had positive outcomes.[191] Immunosuppressed patients without CNS disease should be treated with amphotericin B for 1 to 2 weeks, even in the case of mild presentations, followed by step-down therapy to azoles.

Alternative Antifungal Agents

Voriconazole and posaconazole have demonstrable in vitro activity against *B. dermatitidis*, and voriconazole is listed as a second-line therapy for mild to moderate blastomycosis in Infectious Diseases Society of America treatment guidelines.[206–209] Isavuconazole has in vitro activity against *B. dermatitidis* and has been used for the treatment of patients with blastomycosis, but data are very limited.[154] Although a case of successful treatment of chronic blastomycosis with caspofungin has been reported in a patient with severe allergy to azoles,[210] echinocandins have not been well evaluated for blastomycosis and are not recommended.

Duration of Therapy and Special Populations

Indefinite suppressive treatment may be required if immunosuppression cannot be reversed. For patients with HIV/AIDS, treatment with itraconazole for at least 1 year, CD4 cell counts of >150 cells/mm^3 for at least 6 months, undetectable HIV viral load on ART, and reduction of antigen levels to <2 ng/mL may be used as criteria to discontinue therapy for blastomycosis. Notably, however, these criteria are extrapolated from experience with patients with HIV/AIDS with histoplasmosis.[201] For recipients of solid organ transplantation, immunosuppression should be reduced concomitantly with antifungal treatment.[157] Suppressive therapy following successful treatment may be considered in transplant patients on significant immunosuppression.[157] For all manifestations of blastomycosis, treatment should continue until there is clinical and radiographic improvement or stabilization to residual healed lesions, as well as significant reduction or normalization of serum or urine antigen levels.

Prevention

Patients at high risk for dissemination should avoid activities that expose them to *B. dermatitidis*, such as caving, landscaping, or construction, particularly in areas endemic for blastomycosis. Screening for blastomycosis is not recommended prior to transplantation as the risk of reactivation post-transplant is extremely low.[157]

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is the most serious of the endemic mycoses, with particular proclivity for reactivation, relapse, and treatment failure. An increasing population in the southwestern states, as well as climate-related and anthropomorphic land changes, have placed large numbers of persons at risk. Large outbreaks have been reported in Arizona and southern California in the last decade.[211] Increasing travel through these areas, along with expansion of traditional locations where the organism is considered endemic, have increased the global importance of coccidioidomycosis. *Coccidioides* is listed as a "select agent" of bioterrorism, complicating its use in the clinical and research laboratory.

Epidemiology

Coccidioidomycosis, often referred to as "Valley Fever" (from a San Joaquin Valley outbreak), occurs in a spotty distribution across the southwestern United States, northern Mexico, and Central America (Fig. 133-1). Counties of southern California and southern Arizona are perhaps the most recently well-studied and have experienced an increased incidence of disease.[212,213] Exposure to *Coccidioides* spores is heaviest in the late summer and fall when the soil is dry and conditions are windy. In Kern County, the incidence of coccidioidomycosis has a yearly cycle, with the number of cases generally increasing toward the late fall (17 per month per 100,000 population), decreasing in the winter, and reaching a minimum in the spring and summer.[214] Coccidioidomycosis is laboratory-reportable, and an abundance of information is available, for example, on the Arizona Department of Health website (*www.azdhs.gov/preparedness/epidemiology-disease-control/valley-fever/*).

Coccidioidomycosis is also a common cause of community-acquired pneumonia in the southwest endemic areas.[215,216] Cases are often identified in construction workers, archaeologists, or military personnel. Dust storms (haboobs) can carry the spores for miles, exposing persons with no direct contact with contaminated soil. Many cases occur in individuals with no clear exposure history. Cases are identified outside the endemic area in travelers or past residents of those regions, often years after exposure. Reports of coccidioidomycosis occurring in otherwise healthy young adults[217] and reports of acquisition of disease outside traditionally defined endemic areas contribute to delays in diagnosis.[218,219] Coccidioidomycosis also is a threat to laboratory personnel working with the organism outside of biosafety cabinets. Persons of Black race, Filipinos, and Hispanics experience a disproportionately higher frequency of disease in some studies, although it is not clear whether the predilection is related to genetics or socioeconomic status.[212,220] Notably, coccidioidomycosis is a serious opportunistic infection in immunosuppressed patients, including those with AIDS, transplant recipients, and those receiving immunosuppressive treatment.[221–223]

Mycology

Coccidioidomycosis is caused by the pathogenic fungus *Coccidioides,* which includes two species, *C. immitis* and *C. posadasii.* Except for different geographic locations (*immitis* in California and *posadasii* in Arizona), the laboratory properties, virulence factors, pathogenesis, clinical findings, diagnostic approach, and treatment are mostly identical. Hence, *Coccidioides* will be used to refer to both species in this section.

Coccidioides is highly virulent, causing infection upon exposure to only a few arthroconidia and severe disease with larger inocula. *Coccidioides* has been designated as a select agent by the Centers for Disease Control, requiring that it be ultimately destroyed upon identification in the laboratory except at facilities approved for handling select agents. *Coccidioides* grows as a mold with septate hyphae in the soil and on culture media at room temperature. Its arthroconidia are 2.5 to 4 × 3 to 6 µm in size and function as infectious particles. At body temperature and in clinical specimens, it exists as an endosporulating spherule.

When using special media. Coccidioides converts to an endosporulating spherule at 37° to 40°C. Spherules measure 30 to 60 µm in diameter and contain numerous 2- to 5-µm endospores (Figs. 133-3 and 133-5). In contrast with *H. capsulatum* and *B. dermatitidis*, growth on fungal media occurs rapidly, usually within 3 to 5 days.

Pathogenesis

Infection occurs following inhalation of arthroconidia of the mycelial phase of the fungus or reactivation of latent infection during immunosuppression. Person-to-person transmission does not occur, and direct inoculation of the skin is rare. Donor-derived transmission by transplantation of an infected organ allograft has been reported and causes rapidly progressive disease in the recipient.[224]

In the lungs, the arthroconidia enlarge to form thick-walled spherules, which contain multiple endospores. Spherules rupture releasing endospores, which spread locally and disseminate hematogenously. Cellular immunity and neutrophils are both involved in host defense in coccidioidomycosis.[225] Patients with deficient cellular immunity may experience severe progressive forms of coccidioidomycosis.

Coccidioides infection produces several mixed pyogranulomatous reactions in tissues, which often also contains eosinophils. The neutrophil response and caseous necrosis may lead to the development of large abscesses, which often require surgical drainage. Abscesses may also spontaneously rupture or produce fistulas. Tissue and blood eosinophilia can be prominent.[226]

Clinical Findings

Coccidioidomycosis is asymptomatic in more than one-half of cases. In symptomatic cases, a pulmonary illness is most common, with symptoms appearing 1 to 4 weeks following exposure. True coccidioidal primary infections are difficult to diagnose, since the symptoms of early infection overlap substantially with those of other respiratory infections. While most immunocompetent patients recover without treatment over a course of several weeks, many do receive treatment. Nevertheless, serious infections do occur; in one outbreak following an earthquake, 27% of patients who developed coccidioidomycosis were hospitalized and 1.5% died.[227]

Primary Pulmonary Infection

Symptoms develop within a few weeks following exposure, depending on the size of the inoculum and the immune status of the patient. Low inoculum exposure in the immunocompetent host usually results in a localized pneumonia that may be mistaken for bacterial community-acquired pneumonia. Symptoms include pleuritic or dull chest pain, nonproductive cough, headache, fever, and fatigue.[228] A macular rash, erythema nodosum, and erythema multiforme are common and help to distinguish the infection from bacterial pneumonia. The constellation of fever, arthralgia, and erythema nodosum is referred to as “desert rheumatism.” Infection is more severe in older persons, those with diabetes, and smokers. Diffuse bilateral pneumonia may be associated with an ARDS-type presentation and may occur in the absence of dissemination. A miliary appearance suggests dissemination or fungemia, more often in an immunosuppressed host.

Acute infection typically resolves, even in the absence of treatment, but can set the stage for chronic, progressive disease, which occurs more commonly in immunocompromised individuals, including diabetics. This may result in thick-walled cavities resembling tuberculosis or malignancy. In acute disease, chest radiographs demonstrate patchy infiltrates, often with mediastinal adenopathy. The main CT finding in acute disease is multiple nodules.[229] Typical patterns also include dense lobar consolidation and centrilobular nodules, often with a tree-in-bud pattern.[230] Chronic sequelae include pulmonary nodules in about 20% of cases and thin-walled cavities in 10%. These are usually asymptomatic and may clear without therapy (Fig. 133-7). Residual cavities, however, may become superinfected with bacterial or other fungal organisms or, when in proximity to the pleura, rupture resulting in a pneumothorax, pyopneumothorax, or bronchopleural fistula. When the diagnosis of coccidioidomycosis is not clear, residual and typically asymptomatic nodules are occasionally biopsied or surgically removed, as they mimic malignancy.[231]

Disseminated Disease

Approximately 1% of patients will have disseminated infection, with the most common extrathoracic sites including skin, soft tissue, bone, and meninges.[232] Progressive disseminated disease is, however, reported in nearly one-half of cases, occurring in patients with underlying immunosuppression.[233] Disseminated disease may be first recognized years following exposure. Risk factors for disseminated disease, in addition to immunosuppression, include non-white race, extremes of age, and pregnancy.[220,234,235] Pulmonary involvement is common in disseminated disease; chest imaging usually shows diffuse reticulonodular or miliary infiltrates, although focal pulmonary lesions, nodules, cavities, adenopathy, and pleural effusions also may be seen (Fig. 133-7).

Meningitis is the most common and severe manifestation of disseminated disease; approximately 300 cases are reported in endemic areas per year.[236,237] Patients complain of headache, nausea, vomiting, and confusion. Meningitis carries a poor prognosis and a tendency to relapse despite long-term maintenance therapy. Abscesses may develop in the brain or spinal cord. Hydrocephalus and vasculitis are serious, life-threatening complications of meningitis.

Less frequently involved extrapulmonary sites include liver, peritoneum, kidneys, epididymis, prostate, testes, retina, ears, larynx, heart, thyroid, adrenal, and pituitary gland, esophagus, and pancreas.

Diagnosis

Because the diagnosis of coccidioidomycosis based on clinical and radiographic parameters alone can be difficult, laboratory testing is usually required to establish a diagnosis. A battery of tests, including fungal stain, culture, antigen, and serology, are useful for the diagnosis of coccidioidomycosis (Table 133-9).[76–84,141–143,238–240] The sensitivity of these methods is affected by the extent of exposure, the immune status of the patient, and the type of infection.

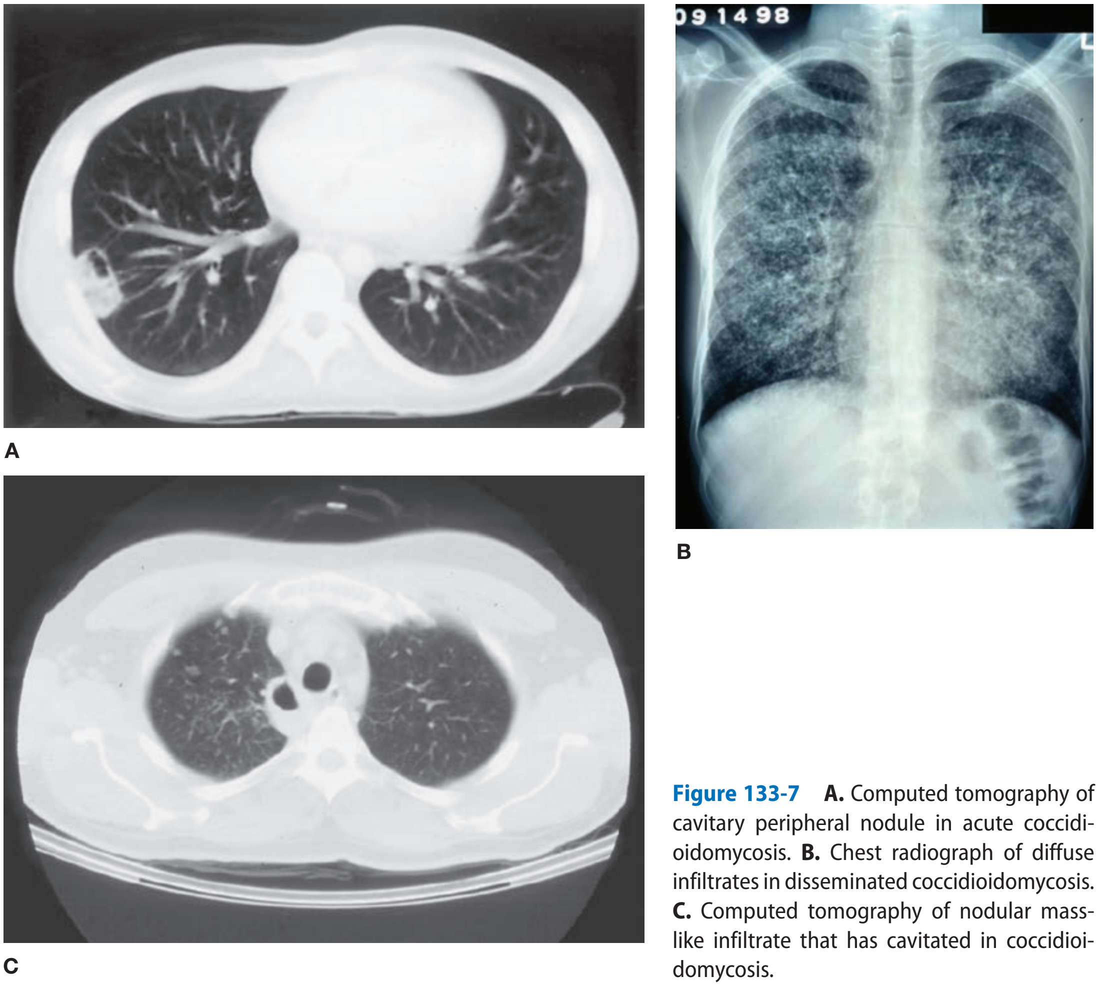

Figure 133-7 **A.** Computed tomography of cavitary peripheral nodule in acute coccidioidomycosis. **B.** Chest radiograph of diffuse infiltrates in disseminated coccidioidomycosis. **C.** Computed tomography of nodular mass-like infiltrate that has cavitated in coccidioidomycosis.

TABLE 133-9 Diagnostic Studies in Coccidioidomycosis (Percent Positive Assays)

Test	Acute Pneumonia, Focal	Acute Pneumonia, Diffuse	Nodule or Cavity	Chronic Fibrocavitary	Disseminated
Papanicolaou smear or histopathology	<25	64	50	35	>75
Culture	<10	86	10	95	39
Serology	90	54	<50	95	95
Antigen	70				

Imaging Studies

The radiologic findings of coccidioidomycosis are diverse (Fig. 133-7).[229,230] Pulmonary infiltrates are identified in the majority of patients, as well as pulmonary nodules and cavities. Pleural effusions and adenopathy are also commonly identified on chest radiographs. Immunosuppressed patients may manifest with a diffuse miliary pattern. CT scans of the chest are more sensitive than chest radiographs, identifying effusions, hilar lymph nodes, micronodular infiltrates, and multifocal ground-glass infiltrates more readily.[241] Pulmonary nodules as sequelae of past coccidioidomycosis infection are usually less than 5 cm in diameter in size but can be confused with malignancy. Nodules rarely calcify; rather, they may evolve into thin-walled cavities with spontaneous excavation of the nodule contents. These cavities may predispose to secondary infection, pneumothorax, hemoptysis, and mycetoma. Lymph nodes and nodules exhibit varying degrees of uptake on PET scans, limiting its utility in distinguishing them from malignancy.[242]

Serology

Serologic tests are the most widely used method of diagnosis for coccidioidomycosis.[232,238,243] Serology is positive in 90% of clinically recognized cases, and the magnitude of response correlates with the extent of infection. However, serology may be negative early in the course of infection, in asymptomatic cases, and in those with mild illness, including thin-walled cavities and solitary nodules. Additionally, immunocompromised patients may have negative serology due to inefficient antibody production.[244] Paired testing 2 to 4 weeks apart may improve sensitivity especially when early disease is suspected. Sensitivity may also be increased by concentrating the specimen, as is done in some reference laboratories.[239]

The immunoglobulin M (IgM) response can be measured by enzyme immunoassay (EIA), tube precipitation, or agar gel diffusion, and is positive in the majority of cases by the end of the first month of the illness, fading over the next 6 months.[239,245] EIA has emerged as the most commonly utilized initial test. False-positive results may occur, and an isolated positive EIA IgM warrants further clinical assessment and diagnostic testing.[246,247] Blair et al.[244] found that EIA was positive in 87% of healthy patients with coccidioidomycosis, compared with 67% of immunosuppressed patients. Sensitivity improved to 95% and 84%, respectively, when sequential and confirmatory tests were employed. Serology may be falsely negative in about one-quarter of solid-organ transplant patients with coccidioidomycosis, and two-thirds to three-quarters if positive EIA results alone are not considered diagnostic.[248]

The immunoglobulin G (IgG) response measured by EIA, complement fixation, or immunodiffusion follows the IgM and peaks during the fourth month of illness, and then slowly fades.[244] The commercial IgG EIA tests are commonly used and are generally highly sensitive and specific. However, the performance characteristics may vary depending on the test used and the performing laboratory.[243,249,250] In the proper clinical setting, a positive result is considered diagnostic. Otherwise, a positive IgG EIA may be sent to specialized reference laboratories for confirmation and quantification. Immunodiffusion quantitative testing or complement fixation testing is often performed as the confirmatory test and provides prognostic information with higher titers (>1:16) suggesting dissemination. However, this finding is neither sensitive nor specific for dissemination, especially in the setting of meningitis.[235] Antibody titers decline with treatment, assisting in monitoring therapy and identifying relapse. Serial testing is also useful in patients who are not receiving therapy, as rising titers suggest progressive infection and support evaluation to exclude dissemination. Detection of complement fixation antibody in CSF is useful for diagnosing meningitis.[237]

Antigen Detection

An enzyme immunoassay using antibodies against *Coccidioides* galactomannan, a cell wall component of *Coccidioides* spp., may be used in conjunction with serologic testing to aid diagnosis. A few studies have highlighted the clinical utility of testing *Coccidioides* galactomannan antigenemia and antigenuria in predominantly immunocompromised patients with moderately severe or disseminated disease. In this severely ill patient population, antigenemia can be detected in up to 71% of urine specimens and 73% of EDTA-treated serum samples.[251,252] Antigen detection in cerebrospinal fluid has been shown to be highly sensitive for the diagnosis of coccidioidal meningitis, with detectable antigen in 93% of cases in one study.[253] In a more recent study of 158 immunocompetent and immunocompromised patients with progressive (severe) coccidioidomycosis that evaluated the performance characteristics of antibody detection by immunodiffusion, as well as *Coccidioides* antigen detection in urine and serum, the sensitivity of urine *Coccidioides* antigen testing was 37% overall but increased to 57% when serum antigen testing was added to urine testing, compared with 84% for serology.[254] The sensitivity of combined antigen urine and serum antigen detection was 79% in disseminated disease, 42% in pulmonary disease, 75% in immunocompromised patients, and 40% in immunocompetent patients. The sensitivity of combined antigen and antibody testing was 93%, supporting the use of both diagnostic modalities for the diagnosis of severe pulmonary or extrapulmonary disease. In real-world settings, antigen testing is most useful in highly immunocompromised patients for whom the sensitivity of serology is suboptimal. Cross-reactivity with other endemic fungi, including histoplasmosis, can occur, and clinical context is needed for accurate diagnosis.[255,256]

Cytology, Histopathology, and Culture

Sputum can be useful for diagnosis, although other respiratory specimens may improve sensitivity. Cytology has been found to be positive in 35% of culture-positive bronchoscopy specimens from patients with pneumonia (specifically, in 46% with diffuse infiltrates and 26% with a focal infiltrate).[257–259] In a study of severe multifocal pneumonia in patients with AIDS, a Papanicolaou smear was positive in 9 of 14 BAL specimens, compared to KOH wet mount in only 3, calcofluor white stain in 2, and culture in 12.[257] Histopathology is positive on needle-biopsy specimens from lung nodules in about one-half of cases.[260] The sensitivity of histopathology in extrapulmonary lesions has not been reported but is presumably high, except for meningitis.

Interestingly, cultures of respiratory specimens are infrequently positive in patients with acute pneumonia. The sensitivity of culture for diagnosis is uncertain because culture positivity is often a basis for inclusion in the published studies. Nevertheless, culture of lung specimens is more sensitive than cytology.[259] Cultures of skin or bone lesions are positive in the majority of cases of disseminated coccidioidomycosis. However, blood, urine, and CSF cultures are frequently negative, complicating the diagnosis. As such, serology and antigen testing play an important complimentary role in the diagnosis of ill patients. Importantly, cultures of *Coccidioides* spp. pose a significant risk for infection to laboratory personnel. Laboratory personnel should be notified if this diagnosis is suspected, and cultures should be handled in a biosafety level 3 laboratory.[232,261]

Polymerase Chain Reaction (PCR)

Once *Coccidioides* is cultivated in the laboratory, confirmation typically occurs via chemiluminescent DNA probe or by DNA sequencing methods, thereby shortening the time to diagnosis. In addition, a few reference laboratories can apply PCR and real-time PCR methodologies directly to clinical samples. Binnicker et al.[262] applied real-time PCR to 66 fresh tissue specimens, yielding 93% sensitivity and 98% specificity when compared with culture. The assay was sensitive enough to be used on paraffin-embedded tissue. Subsequently, clinical sensitivity was shown to be 56% versus 44% for fungal culture, similar to the sensitivity of fungal culture in past studies.[262,263] More recently, Saubolle et al.[264] found that a new real-time PCR assay demonstrated high sensitivity and specificity when compared to culture of bronchial washings or bronchoalveolar lavage fluid. As clinical performance improves and becomes more reliable, molecular methods are likely to become more important for clinical diagnosis in the future.

Skin Test

Skin test reagents were historically used in diagnosis, but this method has fallen out of favor because of a lack of clinical availability and development of newer tests. *Coccidioides immitis* Spherule-Derived Skin Test Antigen (Spherusol) has been approved for the detection of a delayed-type hypersensitivity to *Coccidioides* in individuals with a history of pulmonary coccidioidomycosis. In a real-world assessment of the performance of this test in an endemic region, it was found to be positive in only 72% of proven or probable cases.[265]

Treatment

Guidelines for treatment are continually being updated (Table 133-10).[134,266] Most infections are asymptomatic or self-limited pulmonary infections and require no treatment in the absence of immunosuppression. Before withholding treatment, however, patients must be evaluated carefully for the extent of disease and evidence for extrapulmonary dissemination. Any evidence of dissemination, such as new or persistent headache, skin lesions, inflammatory arthritis, or pain suggestive of osseous involvement, should prompt further investigation and consideration of empiric therapy, pending definitive diagnosis. In patients in whom treatment is withheld, radiographic and clinical follow-up at 4 to 6 weeks and then at 3- to 6-month intervals for 2 years is recommended to identify progressive infection. Patients should be educated regarding the typical course and symptoms of coccidioidomycosis, including those associated with dissemination, and should be considered for reconditioning physical therapy to manage the associated fatigue and deconditioning.[266]

Acute Uncomplicated (Mild) Pneumonia

In minimally symptomatic patients, some physicians recommend treatment to prevent long-term complications, but most recommend observation without therapy. Circumstances warranting treatment include symptoms persisting for 4 to 6 weeks; immunosuppression; other chronic diseases or conditions affecting recovery from the acute infection, such as diabetes, COPD, pregnancy, age greater than 55 years, Black race, or Asians of Filipino descent; and higher severity of illness. Indicators of severe illness include weight

TABLE 133-10 Treatment Recommendations for Coccidioidomycosis Syndromes

Syndrome	Recommendation
Acute pulmonary coccidioidomycosis	
Uncomplicated (mild) infection	Observation
Complicated (moderate to severe) infection	Fluconazole 400 mg/day or itraconazole 400 mg/day for 3–6 months for moderate or prolonged symptoms, risk factors for severe disease
	ARDS/diffuse lung disease: liposomal amphotericin B 5 mg/kg/day until clinical improvement (usually 10–14 days), then fluconazole 400 mg/day or itraconazole 400 mg/day for at least 12 months
Chronic sequelae of coccidioidomycosis	
Pulmonary nodule	No treatment
Pulmonary cavity	No treatment in most cases
	Fluconazole 400 mg/day or itraconazole 400 mg/day for 3–6 months for chronic fibrocavitary disease until symptoms/cavity stabilize
	Surgical resection for persistent or massive hemoptysis, cavity rupture with pneumothorax
Disseminated coccidioidomycosis	
Nonmeningeal and mild–moderate	Fluconazole 400 mg/day or itraconazole 400 mg/day for at least 1 year until clinical stability/improvement
Nonmeningeal and severe	Liposomal amphotericin B 5 mg/kg/day for severe cases until clinical improvement (usually 10–14 days) followed by transition to oral azole therapy as above
Meningitis	Fluconazole 400–1000 mg/day or itraconazole 600 mg/day for life
	Intrathecal amphotericin B in rare cases
	CSF shunt for hydrocephalus

loss greater than 10% of body weight, intense night sweats for more than 3 weeks, infiltrates involving more than one-half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, and inability to work.[134] Treatment is indicated in all patients with diffuse pulmonary or disseminated coccidioidomycosis.[134,266]

Acute Complicated (Moderate to Severe) Pneumonia

Fluconazole is used in the majority of outpatients and those with mild to moderate coccidioidal pneumonia. Consultation is warranted for patients with severe or extrapulmonary disease or with underlying immunosuppression. Liposomal amphotericin B (5 mg/kg/d), generally preferred over nonlipid formulations for its lower nephrotoxicity profile, is indicated as initial therapy in severe cases with subsequent transition to oral azole therapy.

Non-CNS Extrapulmonary Disease

Itraconazole and fluconazole are effective in milder nonmeningeal cases. In patients with bone disease, outcomes have been better with itraconazole.[267,268] Recommended dosages for fluconazole and itraconazole are 400 mg/day for nonmeningeal disease. Drug interactions and inadequate drug exposure occur more often with itraconazole than fluconazole. Patients with severe disease should receive induction with liposomal amphotericin B 5 mg/kg/day until clinical improvement (usually 10–14 days), followed by transition to oral azole therapy.

CNS Disease

Treatment for meningitis is less effective than for other forms of coccidioidomycosis. Fluconazole, 400 to 1000 mg per day (typically, 800 mg per day at initiation) is recommended because of excellent penetration into CNS.[134,269] Some physicians also administer amphotericin B intrathecally, although this is more commonly done for cases refractory to azole therapy.[270] For patients in whom hydrocephalus develops, administration via a ventricular Ommaya reservoir facilitates intrathecal therapy. Consultation with an infectious disease or pulmonary physician who specializes in coccidioidomycosis treatment is advised. Because the presence of CNS coccidioidomycosis is often associated with non-CNS extrapulmonary disease, many experts add intravenous liposomal amphotericin B to fluconazole. Treatment for coccidioidal meningitis requires lifelong suppressive therapy with fluconazole (or itraconazole) due to a high risk of recrudescent disease with cessation of therapy.[271,272] Response to therapy, including assessment of symptoms, imaging features, and CSF analysis, must be documented. In those with an inadequate response, escalating doses or intrathecal amphotericin B is recommended.[266]

Persistent Cavities or Nodules

Approximately 10% of patients with acute pulmonary coccidioidomycosis will develop residua of acute infection (nodules or cavities), which are often asymptomatic and require no therapy. However, these residua can lead to complications, including pain, cough, hemoptysis, and bacterial superinfection. Antifungal therapy is appropriate in patients with persistent symptoms or rising serologic titer. Treatment is also recommended in those with lesions contiguous with the pleura or exhibiting progressive enlargement, such as patients with chronic fibrocavitary disease. Biopsy of nodules may be required if a history of infection is not secure in order to exclude malignancy.

Alternative Antifungal Agents

The newer triazoles posaconazole, voriconazole, and isavuconazole exhibit in vitro and in vivo activity against *Coccidioides,* and there are several reports of successful treatment, including cases of meningitis.[152,273] Because of poor in vitro activity and inconsistent results, caspofungin and other echinocandins are not currently recommended.

Duration of Therapy and Special Populations

In patients with acute pulmonary coccidioidomycosis, up to 3 months of therapy may be sufficient. Patients should be re-evaluated before treatment is stopped to identify evidence for chronic infection or extrapulmonary dissemination, in which case treatment should be continued for 12 to 18 months or longer. Prolonged therapy may be considered in patients with underlying immunodeficiency, although duration of therapy in these populations is generally similar to that in immunocompetent patients.[134,157,266]

Immunocompromised patients, such as those with hematopoietic stem cell or solid organ transplant, those on biologic response modifiers, and individuals with HIV infection and CD4 counts less than 250 cells/mm^3, are at higher risk for severe and disseminated infection and should be treated regardless of severity at the time of diagnosis.[157] Treatment is generally similar for immunocompetent patients, with oral azole therapy considered first-line, with the exception of severe or refractory disease, for which liposomal amphotericin B is recommended as initial or rescue therapy, respectively.[266] In solid organ transplantation, maintenance immunosuppression should be reduced concomitantly with antifungal treatment.

There is also a real risk of relapse of coccidioidomycosis after discontinuation of antifungal therapy, so lifelong suppressive therapy with azoles (fluconazole 200–400 mg daily) is usually recommended unless complete withdrawal of immunosuppressive therapy is achievable.[157] Pregnant women are also at higher risk for severe disease, but the teratogenicity of azole therapy complicates treatment. For those who develop symptomatic disease during pregnancy, treatment should be strongly considered with a preference for amphotericin B during the first trimester and oral azole therapy thereafter. Coccidioidal meningitis during the first trimester of pregnancy is preferentially treated with intrathecal amphotericin.[266] As discussed above, treatment should be continued indefinitely for patients with meningitis or those with severe underlying immunodeficiency states, regardless of the underlying host.[134,266]

Adjunctive Surgical Therapy

Surgical debridement or resection of infected tissue often is necessary as an adjunct to antifungal therapy. Cavitary disease that results in persistent symptoms despite antifungal therapy should be considered for surgical resection, preferably by video-assisted thoracoscopic surgery. For cavities that rupture into the pleural space, drainage is required, preferably with decortication and surgical resection of the cavity rather than tube thoracostomy alone.[231,266,274] Hydrocephalus may require surgical intervention with placement of a shunt. Soft tissue, joint, or bony abscesses may require drainage or debridement.[268]

Adjunctive Steroid Therapy

Although not routinely used, corticosteroid therapy plays a limited role as adjunctive therapy in coccidioidomycosis. An intense eosinophilic pneumonia can occur resembling a hypersensitivity reaction and clinical improvement has been noted with concomitant steroid therapy.[226,275] Corticosteroids may also be of utility as adjunctive therapy in coccidioidal IRIS.

■ Prevention

Recommendations exist for the prevention of coccidioidomycosis in high-risk occupations.[276] Patients with diseases that impair cellular immunity probably should avoid activities involving dust or soil, areas experiencing active outbreaks, and the desert during dry and windy periods. Death from coccidioidomycosis was reduced by antifungal therapy used as secondary prophylaxis in solid-organ transplant patients with a history of symptomatic coccidioidomycosis up to 5 years before transplantation, supporting a recommendation for preventive treatment.[277] As such, primary antifungal prophylaxis is recommended for organ transplant recipients who have lived or are living in endemic areas in the first 6 to 12 months after transplantation.[266,278] Serologic screening for coccidioidomycosis prior to transplant is recommended, with seropositive patients receiving prophylaxis with fluconazole 400 mg daily, and seronegative patients (who continue to reside in endemic areas) receiving 200 mg daily. In lung transplant recipients, some experts recommend lifelong prophylaxis.[157,222,279] Solid-organ transplantation should be delayed in any patient with active coccidioidomycosis until the infection is well controlled or resolved. In persons with HIV/AIDS with a CD4 count less than 250 cells/mm^3 living in *Coccidioides*-endemic areas, serologies should be checked yearly. Those with positive IgG on initial testing or who seroconvert from negative to positive should be placed on primary prophylaxis with fluconazole.[266,279] Although prophylaxis is not generally recommended for patients on biologic immunomodulatory therapy, individuals in endemic regions should undergo screening for coccidioidomycosis by chest radiograph and serology prior to initiating therapy; treatment of those with positive results is recommended before starting biologic therapy.[280] Efforts to develop a vaccine to prevent coccidioidomycosis in humans have been unsuccessful to date, but are ongoing.[281]

CHAPTER 134

Pneumocystis Pneumonia

Eliezer Zachary Nussbaum
Marwan M. Azar

INTRODUCTION

Pneumocystis is an opportunistic yeast-like fungus that is tropic to mammalian lung tissue and produces a clinical spectrum ranging from asymptomatic infection to subacute and acute interstitial pneumonia in susceptible hosts. The earliest descriptions of *Pneumocystis jiroveci* pneumonia (PCP) in humans came from reports of malnourished children and neonates with pneumonia in the 1940s, but the syndrome came into worldwide prominence during the HIV/AIDS pandemic in the 1980s where PCP accounted for more than one-fourth of community-acquired pneumonias in persons living with HIV/AIDS (PLWH). The subsequent introduction of combination antiretroviral therapy (ART) and institution of routine PCP prophylaxis for those at greatest risk of infection led to a decreased incidence of PCP among PLWH. In the developed world, HIV-negative patients with cell-mediated immune deficiencies have become the most common hosts for PCP, with 60% to 70% of new infections occurring in patients on prolonged high-dose corticosteroids and chemotherapeutic agents as well as those with autoimmune diseases or recipients of solid organ or hematopoietic stem cell transplantation.[1–3] Although it produces a characteristic interstitial pneumonia for which effective treatments are available, *Pneumocystis jiroveci* has remained a problematic pathogen due to an enlarging population of at-risk individuals, a propensity to colonize hosts for short periods of time without necessarily causing infection, an ability to produce fulminant infection despite low pathogen burdens, intrinsic resistance to the most common antifungal classes, and the inability to sustain and thus study the organism in vitro.

HISTORY AND BACKGROUND

The fungus *Pneumocystis,* a unicellular, host-specific yeast-like organism, is unusual among fungi in many respects including its history. First described by Carlos Chagas in 1909, *Pneumocystis* was mistakenly interpreted as a developmental stage of the protozoan *Trypanosoma cruzi* and classified as a parasite until years later when genetic analyses revealed the organism to be more closely related to fungi.[4] In 1912, the organism infecting rat lung tissue was understood by Delanoe and Delanoe to be separate from the trypanosome and named *Pneumocystis carinii*, but *Pneumocystis* was not recognized as a pathogen of humans until 1942 (Van der Meer and Brug).[5,6] The first descriptions of a syndrome consistent with PCP came from orphanages in Europe in the 1930s and following World War II and the Vietnam War where clusters of "plasma cell interstitial pneumonitis" were reported among disadvantaged children and neonates.[7] It was not until 1952 that a clear association with human disease was made by Vanek and Jírovec.[7] In addition to severe malnutrition, prolonged corticosteroids and chemotherapeutic agents were recognized as risk factors for PCP.

In the 1970s, the Centers for Disease Control and Prevention (CDC) undertook epidemiologic and therapeutic studies to better characterize the host–pathogen interaction and to broaden the antimicrobial armamentarium beyond pentamidine, which was the only available therapeutic option at the time. This investigation resulted in the development of pyrimethamine, sulfadoxine, trimethoprim (TMP), and sulfamethoxazole (SMX), agents that are highly effective in treatment and prevention of PCP. In the 1980s, the rise of the HIV/AIDS pandemic was accompanied by an explosion in the incidence of PCP presenting as an AIDS-defining opportunistic infection, with more than 200,000 cases since 1979. In 1976, Frenkel described serologic differences between organisms recovered from humans and rats suggestive of the existence of distinct species, and in 1988, rRNA analysis indicated that *Pneumocystis* was more closely related to fungi.[4] Currently, a unique species of *Pneumocystis* has been described as pathogenic for almost every mammal, although the basis for this specificity is as of yet unknown.[8] Although both *carinii* and *jirovecii* have been used interchangeably in the medical literature, *P. jiroveci* is now understood as the organism that infects humans while *P. carinii* is the pathogen of rats. Despite the change in nomenclature, PCP continues to be the preferred abbreviation for the pneumonia syndrome.[9]

PATHOGEN

Pneumocystis is an extracellular, obligate ascomycetous yeast-like fungus that is mostly restricted to lung tissues with rare exceptions of extrapulmonary infection, mainly in highly immunosuppressed hosts with structural lung disease and heavy organism burdens. Morphologic forms of the *Pneumocystis* life cycle continue to be designated in terms of cysts and trophozoites, a relic of the organism's taxonomic past. *Pneumocystis* organisms carry a variety of surface glycoproteins, some of which are unique to different species.[10] Unlike most fungi, *Pneumocystis* lacks ergosterol in its cell membrane, but is instead rich in cholesterol like mammalian cells. Commonly used antifungal medications that target ergosterol biosynthesis, such as azoles and the polyene amphotericin B, are therefore ineffective against this organism.[11] The cell wall of *Pneumocystis* is also characterized by low amounts of chitin and an abundance of other polysaccharides including glucose, mannose, and (1,3)-β-D glucan, a biologic feature that has been exploited for the development of highly sensitive peripheral antigenic testing in the setting of clinical infection (particularly targeting peripheral detection of [1,3]-β-D glucan) and as a therapeutic target for echinocandin antifungal agents (which bind [1,3]-β-D glucan). *Pneumocystis* species demonstrate high degrees of host specificity with *P. jirovecii* acting as a human pathogen, *P. carinii* a rat pathogen, and *P. murina* a mouse pathogen among many others with no cross-infection across mammalian species. Growth of *Pneumocystis* cannot be sustained in in vitro culture beyond a few replication cycles. As such, culture is not an available diagnostic tool for this fungus. Furthermore, lack of culture capability has hampered research on the organism's life cycle, metabolic functions, and potential targets for drug therapy.

MORPHOLOGIC FORMS AND LIFE CYCLE

Pneumocystis exists in three predominant morphologic forms: the trophozoite (2–5 μm in size), the mature cyst (3–8 μm in size), and the precyst (3–8 μm in size), although other intermediate developmental stages exist. Trophozoites are single-celled, thin-walled, and ameboid in shape, and they exhibit pseudopodia and filopodia used for limited motility and/or anchoring to host cells. Mature cysts are thick-walled and globular and contain up to eight sporozoite or intracystic bodies (1 μm in size), the majority of which are haploid. In the setting of *P. jirovecii* pulmonary infection, trophozoites are 10-fold more abundant than cyst forms in respiratory clinical specimens. Mature cysts likely allow *Pneumocystis* to subsist outside of

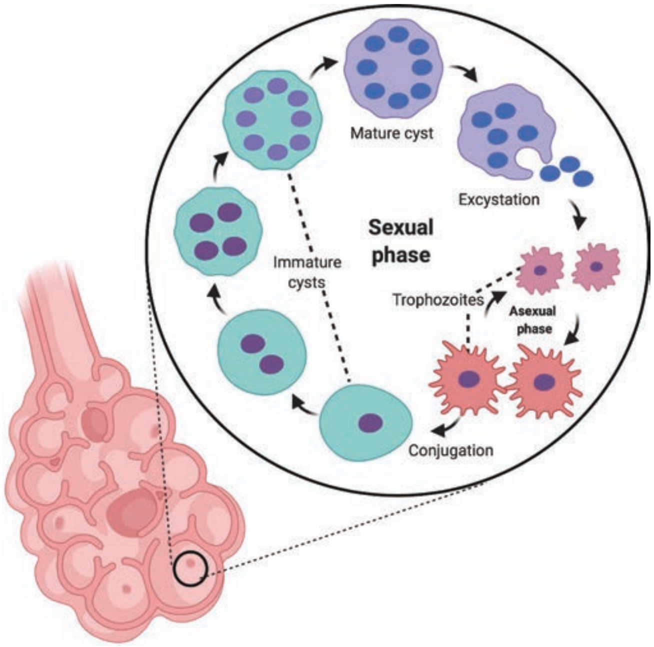

Figure 134-1 *Pneumocystis jirovecii* proposed life cycle within the human lung. Mature cysts undergo excystation to numerous sporozoites into lung tissue. Sporozoites then develop into trophozoites, which proliferate by binary fission to produce more trophozoites in an asexual cycle. Alternatively, two haploid trophozoites can undergo conjugation into an immature cyst (or precyst), which then progressively matures into a full cyst.

lung tissue and appear to be essential for transmission of infection to other hosts.[12,13] Precysts are immature cysts that contain up to eight developing sporozoites depending on the stage of maturation. Precysts do not have well-defined sporozoites, and their cell wall progressively thickens as they mature.[14] *Pneumocystis* organisms do not bud, which distinguishes them from most other yeasts and yeast-like organisms.

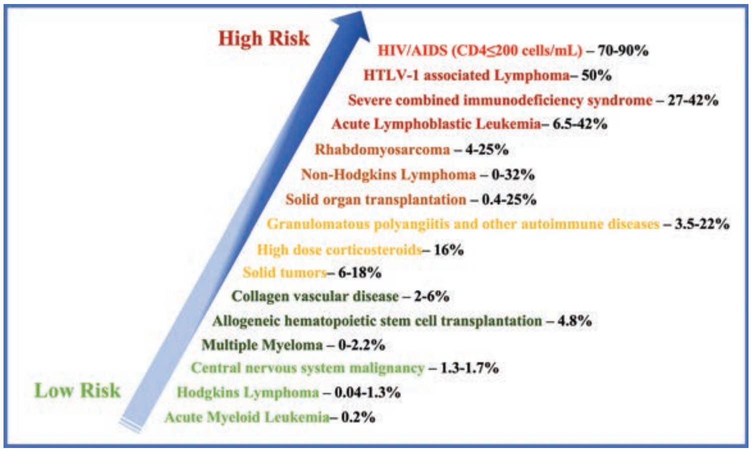
Owing to the inability to sustain continuous growth in culture, the *Pneumocystis* life cycle is incompletely understood and knowledge is derived from animal models of infection or microscopic analyses of clinical specimens, neither of which is fully representative of the entire human life cycle. Mammalian infection may begin when aerosolized mature cysts are inhaled into terminal alveoli. In a putative life cycle, the mature cysts then undergo excystation to release numerous sporozoites into lung tissue (Fig. 134-1). In the asexual phase, sporozoites develop into trophozoites that proliferate by binary fission to produce more trophozoites. Trophozoites can also attach to one another to form clumped trophic forms that are seen during infection. In a proposed alternate sexual phase, two haploid trophozoites undergo conjugation into a precyst diploid form, which then progressively matures into a full cyst (Fig. 134-1).[15]

EPIDEMIOLOGY AND RISK FACTORS

Pneumocystis is ubiquitous worldwide. The organism is likely acquired early in life based on the near universal seropositivity of humans by 2 to 4 years of age.[16,17] Primary infection either presents as a mild respiratory illness or is completely asymptomatic. In an early model of *Pneumocystis* infection, the organisms were thought to settle into quiescence for years to decades after primary infection, reactivating only in the event of T-cell immune compromise. Though instances of prolonged latency are possible, colonization with *Pneumocystis* appears to be more transient with frequent re-exposures leading to short-lived re-infections throughout life. Person-to-person transmission of *Pneumocystis* has been strongly suggested among normal and immunocompromised hosts. In the absence of a known epidemiologic niche, humans have themselves been proposed as the reservoir. The mode of transmission is thought to be airborne via close proximity with an infected host. Studies in animal models suggests that close contact for 24 h may be sufficient for transmission to other hosts, and studies of air samples from clinics, bronchoscopy suites, and hospital rooms of patients with PCP have identified genotypically identical aerosolized organisms by polymerase chain reaction (PCR).[18,19] Outbreaks of PCP have occurred among children and immunosuppressed patients, particularly liver, kidney, and heart transplant recipients, with *Pneumocystis* strain genotyping showing a common source of infection and suggesting either interhuman transmission or a common environmental source of infection.[20,21] Despite these concerns, there has been insufficient evidence to recommend isolation of all patients with documented PCP. CDC infection control guidelines recommend standard precautions with the added suggestion of avoiding placing an immunocompromised patient in the same hospital room as a patient with PCP.[22] Treatment of active infection and prophylaxis for those at risk remain the most effective prevention methods for PCP. Although neutropenia and hypogammaglobulinemia enhance the risk of PCP by contributing to the overall net state of immunosuppression, T-cell dysfunction is the primary risk factor for development of PCP. Susceptible individuals include PLWH, HIV-negative immunocompromised individuals with innate or acquired T-cell dysfunction, and malnourished infants or neonates.

In the early HIV/AIDS era, PCP became the most common AIDS-defining condition, affecting 75% of all PLWH.[23] Although the incidence has since decreased, PCP remains one of the most common opportunistic infections in this population.[24] Currently about 40% of patients who develop PCP have underlying HIV/AIDS.[1] In the absence of effective prophylaxis or ART, 66% to 85% of patients with AIDS are likely to develop PCP.[25,26] The main risk factor for development of PCP in the setting of HIV-infection is a peripheral CD4 T-cell count of <200 cells/μL, as progressive depletion of CD4+ T cells hinders an effective cellular response to the pathogen. The incidence of infection increases by 100% when peripheral CD4+ lymphocyte counts decrease from 100 to 200 cells/μL to below 100 cells/uL.[25,27] Additional risk factors include a CD4 T-cell percentage of <14%, as well as other indicators of poor cellular immunity including a previous history of PCP and oral candidiasis irrespective of CD4 count, higher HIV RNA levels in plasma, and malnutrition.[28,29] HIV viral load is a strong independent predictor of PCP, and evidence is mounting that patients with suppressed viral load are at very low risk of PCP even in the setting of CD4 counts of 100 to 200 cells/μL.[30] PCP can rarely occur with a CD4 T-cell count of >200 cells/μL. This may be a consequence of superimposed risk factors such as concurrent use of corticosteroids or immune senescence from advanced age but may also be reflective of subtle qualitative immune deficits as a result of impaired T-cell repertoires in patients with a history of profound AIDS and very low CD4 T-cell count nadirs.[31] Additionally, PCP may manifest with CD4 T-cell recovery after institution of ART as a part of the immune reconstitution syndrome.

In the current era, the majority of PCP cases occur in HIV-negative immunocompromised patients with impaired T-cell function. The highest incidences are in patients with HTLV-1 associated lymphoma (50%), severe combined immunodeficiency syndrome (27%–42%), acute lymphocytic leukemia (6%–45%), rhabdomyosarcoma (4%–25%), and non-Hodgkin lymphoma (0%–32%). Solid organ transplantation (0.4%–25%), allogeneic bone marrow transplantation (4.8%), and other conditions including non-cancer patients receiving prolonged courses of steroids in high doses also are at risk (Fig. 134-2).[32] For recipients of solid-organ transplantation, the risk is greatest within the first 6 months after transplantation, during periods of increased immune suppression, as with the use of pulse corticosteroids or lymphocyte depletion for graft rejection and with recent cytomegalovirus (CMV) infection.[33] Approximately 70% of PCP infections in solid-organ transplant recipients are associated with a CD4 T-cell count less than 200 cells/μL and an absolute lymphocyte count less than 500 × 10^6 cells/μL.[34,35] Solid-organ transplant recipients receiving sirolimus-based immunosuppression may rarely develop an idiosyncratic diffuse pneumonitis that mimics PCP.[36] Patients with primary immunodeficiencies including idiopathic CD4 T-cell lymphocytopenia also are at risk. The use of corticosteroids has been identified in up to 90% of HIV-negative patients with PCP.[37] In one study of HIV-negative patients with PCP, the median dose of prednisone was 30 mg/day for 12 weeks, although 25% received a prednisone dose of 16 mg for 8 weeks or fewer.[38] A lower peripheral lymphocyte count is associated with an increased risk for PCP in HIV-negative patients, but the correlation is weaker than for HIV positive patients. The use of corticosteroids and other immunosuppressive agents also confounds this relationship.[39] CD4 counts are most likely to be useful for risk prediction if they are low or low in comparison with baseline or previous values.



High Risk
HIV/AIDS (CD4≤200 cells/mL) – 70-90%
HTLV-1 associated Lymphoma– 50%
Severe combined immunodeficiency syndrome – 27-42%
Acute Lymphoblastic Leukemia– 6.5-42%
Rhabdomyosarcoma – 4-25%
Non-Hodgkins Lymphoma – 0-32%
Solid organ transplantation – 0.4-25%
Granulomatous polyangiitis and other autoimmune diseases – 3.5-22%
High dose corticosteroids– 16%
Solid tumors– 6-18%
Collagen vascular disease – 2-6%
Allogeneic hematopoietic stem cell transplantation – 4.8%
Multiple Myeloma – 0-2.2%
Central nervous system malignancy – 1.3-1.7%
Low Risk
Hodgkins Lymphoma – 0.04-1.3%
Acute Myeloid Leukemia– 0.2%

Figure 134-2 Incidence of PCP in HIV-positive and HIV-negative immunocompromised populations.

CLINICAL PRESENTATION

Infection with *P. jirovecii* most often presents as a pulmonary syndrome characterized by hypoxemia, dyspnea, and cough, commonly out of proportion to physical exam or radiologic findings. Notably, the clinical course often manifests differently in PLWH and HIV-negative patients, a clinical distinction that has become more apparent with the rise in prevalence of infection in HIV-negative immunocompromised hosts.

■ Persons Living with HIV

PLWH with PCP classically present with fever, cough, dyspnea, and hypoxemia. HIV-infected hosts characteristically experience subacute and insidious progression of symptoms over the course of several weeks.[40–43] Patients generally present to medical attention between 2 and 8 weeks after symptom onset with a median time to diagnosis of 21 days after symptom onset.[1,44] Fever is often low grade, cough is typically nonproductive, and frank tachypnea is present in just over half of patients. Hypoxemia is initially mild and may only be observed with exercise or exertion so an ambulatory oxygen saturation test may be revealing. Fewer than 10% of patients are completely asymptomatic. Physical exam findings can be subtle, and lung auscultation is often normal. Inspiratory crackles are the most commonly encountered abnormal pulmonary exam finding.[40]

■ HIV-negative Hosts

PCP among HIV-negative immunocompromised hosts often presents as a more severe respiratory illness, sometimes with fulminant disease. Clinical manifestations are still characterized by dyspnea, hypoxemia, fever, and minimally productive cough; however, the onset and progression of symptoms tends to be more rapid and severe compared with PLWH. The average time from symptom onset to presentation is less than 1 week. Patients often require higher levels of supplemental oxygen support, are more likely to necessitate mechanical ventilation and ICU admission, and are more likely to develop hemodynamic compromise.[42–46] Accordingly, reported mortality rates in this population have been higher than for the HIV-positive population.[43–45] However, with improvements in diagnostic techniques and increased awareness of PCP among HIV-negative patients, less severe and more indolent presentations are increasingly observed in this population, perhaps due to earlier recognition and diagnosis.

The discordance in clinical presentations among HIV-positive and -negative patients appears to be related to differing inflammatory responses to infection. Patients with HIV/AIDS typically have a higher burden of organisms, but an ineffective and/or less rigorous host immune response may dampen inflammation within the lungs and manifest with less aggressive symptomatology. Indeed, in one study, patients with AIDS and PCP had both lower BAL neutrophil counts and higher arterial oxygen tension than non-HIV immunocompromised patients with PCP, even in the absence of microorganisms other than *P. jiroveci.*[47] In non-HIV/AIDS patients, the inflammatory response tends to be more robust, leading to more severe clinical symptoms despite a smaller organism burden in the lungs.[41,44] In addition, the smaller inoculum makes diagnosis more challenging, which can lead to diagnostic and therapeutic delay. This immunologic interplay further informs our understanding of risks of disease acquisition among HIV-negative patients over time. In the organ transplant recipient, PCP most frequently occurs approximately 2 to 4 months after initiation of immune suppression as well as during periods of increased immune suppression (pulsed corticosteroids, antilymphocyte therapies). Severe presentations may also occur when immunosuppression is abruptly decreased, since immune reconstitution allows for a more robust inflammatory response to even a small organism burden.

In both populations, coinfection with other organisms may accelerate progression of disease and effect the clinical presentation. In particular, CMV, *Histoplasma capsulatum*, *Legionella* spp., and mycobacterial species may contribute to symptomatology and influence the clinical syndrome. Coinfection with CMV and other pathogens is detected in many *Pneumocystis*-infected patients and likely plays a role in the individual immune response of each patient.[38,48] In addition, the rate of development and severity of clinical infection is exacerbated by the presence of pre-existing lung disease (e.g., pulmonary fibrosis).

EXTRAPULMONARY PNEUMOCYSTOSIS

Extrapulmonary infection with *Pneumocystis* is rare. The incidence among PLWH has been estimated at 0.06% to 0.53%.[49,50] Risk factors for extrapulmonary spread of *Pneumocystis* infection have not been established, but use of inhaled pentamidine for prophylaxis was once considered a risk factor because of poor systemic absorption. However, the incidence of extrapulmonary infection among patients on aerosolized pentamidine for primary or secondary PCP prophylaxis appears to be low, with 6 reported cases in a total of 1099 combined patients from several published studies, for an overall incidence of 0.5%.[51] Conversely, cases of extrapulmonary *Pneumocystis* in patients receiving systemic prophylaxis have been reported, including in 2 patients on dapsone-pyrimethamine prophylaxis.[52,53] Although it is not clear from the available evidence that inhaled pentamidine prophylaxis is inadequate to prevent extrapulmonary spread, the low incidence of disease prevents an accurate measurement of risk or incidence so it continues to be a theoretical concern.

Extrapulmonary pneumocystosis has been described in both HIV-positive and HIV-negative individuals. Infection may occur concurrently with lung involvement or with minimal or absent respiratory disease. Sites of extrapulmonary infection include the liver, spleen, lymph nodes, thymus, thyroid, skin, eye, ear, mastoids, muscles, peritoneum, gastrointestinal tract, omentum, pleura, kidney, bone marrow, pancreas, adrenal glands, meninges, and cerebral cortex. Hematogenous dissemination was evident in several cases in which *Pneumocystis* was detected in the lumens of large blood vessels during autopsy.[51] *Pneumocystis* has also been associated with the development of venous thromboembolism and, rarely, with vasculitis leading to ischemic necrosis of the digits.[54] The most common disease presentation is that of a mass lesion or abscess along with fever and constitutional symptoms with the addition of organ-specific symptoms (such as visual loss with choroidal involvement), signs (ascites with peritoneal lesions), or laboratory abnormalities (transaminase elevations with liver impairment). In contrast with pulmonary infection, which tends to be more acute and symptomatic in HIV-negative patients, extrapulmonary infection appears to be more clinically evident in HIV-infected persons with symptoms associated with the involved organs. Additionally, disease restricted to the ear and eye has mainly been observed among HIV-infected individuals.[51]

Demonstration of *P. jirovecii* organisms in affected tissues confirms the diagnosis of extrapulmonary pneumocystosis. The presence of typical foamy eosinophilic material within extrapulmonary tissues is a clue to the diagnosis and should prompt additional investigation for pneumocystosis with special staining. Histopathology will often demonstrate granulomatous inflammation or the presence of cavities.[55] Calcifications may be seen in infected tissues, especially within the parenchyma of the liver and spleen but also in other sites such as the pleura or thyroid gland.[56] Computed tomographic (CT) scan findings include focal, nonenhancing lesions with low attenuation in various organs but most commonly the liver and spleen, often with rim-like or punctate calcification and/or necrosis and/or hemorrhage (Fig. 134-3). Based on published studies and expert opinion, medical treatment of extrapulmonary *Pneumocystis* infection is usually successful without the need for surgical drainage. There is no preferred systemic agent for extrapulmonary pneumocystosis, and treatment typically consists of the same regimens used for pulmonary disease.

RADIOLOGIC PATTERNS OF PNEUMOCYSTIS PNEUMONIA

Lung imaging plays an important role in the evaluation of patients with PCP. Chest x-rays and CT scans are the most frequently utilized imaging modalities. Typical radiologic features include diffuse, bilateral, interstitial infiltrates and ground-glass opacities. Less

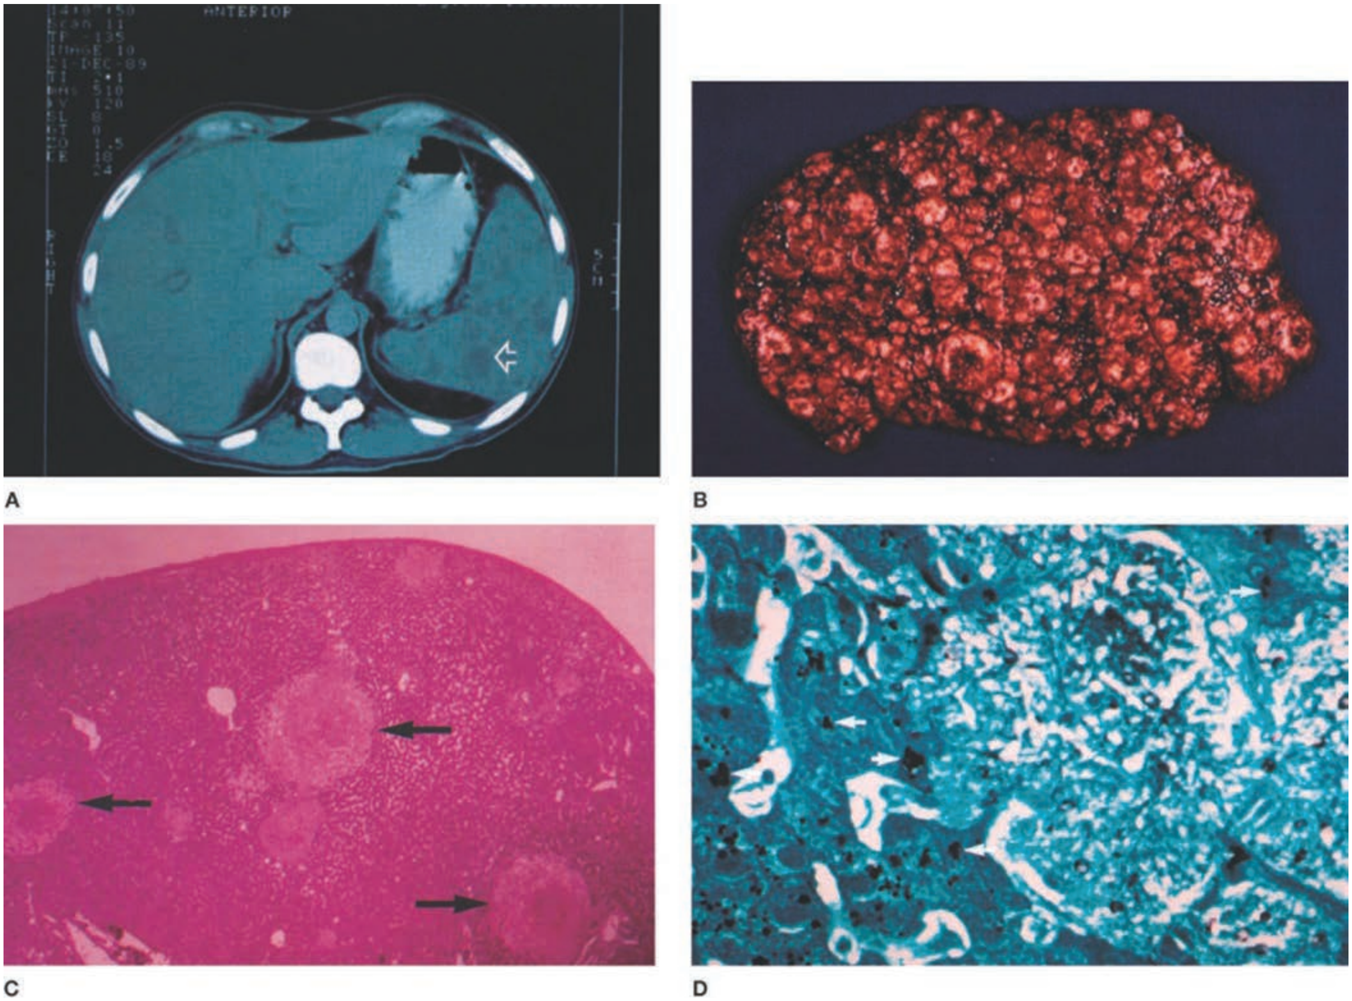


Figure 134-3 Extrapulmonary pneumocystosis in a patient with AIDS on aerosolized pentamidine prophylaxis presented as a splenic mass lesion with abdominal pain. The computerized body tomographic (CBT) scan reveals a mass lesion **(A)**, seen after splenectomy on gross pathology (**B**), and on microscopic examination (hematoxylin and eosin stain, **C**. Silver stain, **D**). *(Reproduced with permission from Dr. J. Davis Allen, Jr., New England Deaconess Hospital.)*

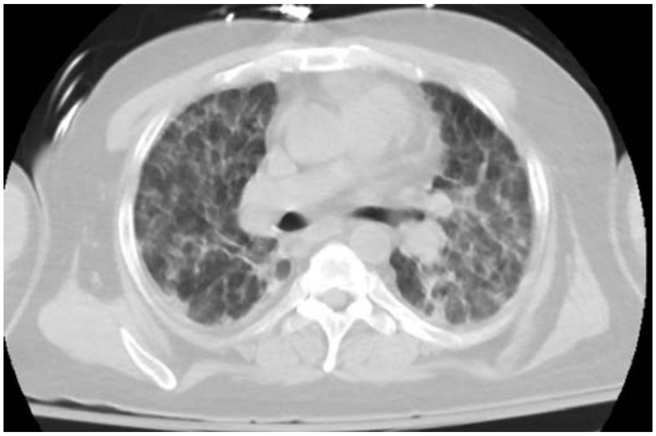

Figure 134-4 Bilateral diffuse ground-glass opacities and septal thickening in a patient with PCP.

common radiologic findings include pulmonary cysts, pneumothoraces, lobar consolidations, and pulmonary nodules.

Interstitial Pattern

The classic imaging finding in PCP is a bilateral interstitial pattern, characterized by extensive ground-glass opacities (Fig. 134-4). This appearance likely represents the accumulation of fibrin, debris, and organisms within alveoli as well as interstitial inflammation.[57] On conventional chest x-rays, this appears as fine, bilateral, perihilar, diffuse infiltrates that can progress to an interstitial alveolar butterfly pattern, characterized by a central predominance of opacities with a clear zone at the periphery of the lobes. Early in the course of disease and in patients with AIDS, chest x-rays are less sensitive and may demonstrate normal or only subtle findings.[57,58] Chest CT is a more sensitive imaging modality and is helpful when clinical suspicion remains high despite a normal chest x-ray. The classic chest CT finding is that of extensive ground-glass attenuation, which may be diffuse, mosaic, or predominantly central in distribution.[57–60] This interstitial pattern is also classically observed in patients who undergo nuclear imaging when chest CT cannot be obtained; however, this modality is rarely used in the current era.

Pulmonary Cysts

Pulmonary cysts can be seen in as many as many as one-third of patients with PCP and are more likely to develop in AIDS patients.[57] Lung cysts can vary in appearance, although they tend to have thin walls and may range from several millimeters to several centimeters in size (Fig. 134-5). When present, cysts are often numerous and occur in multiple lung segments. The pathogenesis of these cystic lesions is incompletely understood but is theorized to relate to bronchiolar obstruction, elastase release from macrophages, and direct tissue destruction from the organism itself.[61] Cysts typically resolve after successful treatment. Notably, cyst rupture may lead to spontaneous pneumothorax.

Pneumothorax

Pneumothorax is reported to occur in anywhere from 5% to 20% of patients with PCP and is more common in PLWH.[60,62] This finding is most frequently detected via either chest x-ray or CT of the chest (Fig. 134-6). Pneumothoraces most commonly occur spontaneously as sequelae of ruptured cysts; however, they may also develop even in the absence of identifiable cystic disease, as well as iatrogenically from barotrauma secondary to mechanical ventilation or from complications of other procedures such as thoracenteses. In addition, patients who receive aerosolized pentamidine as prophylaxis appear to be at greater risk for spontaneous pneumothorax. Breakthrough disease has been well described after use of inhaled pentamidine, and classically presents largely or solely in the upper lobes. Bullous or cystic changes may then develop in the lung apices, increasing the risk of spontaneous pneumothoraces.[60,63]

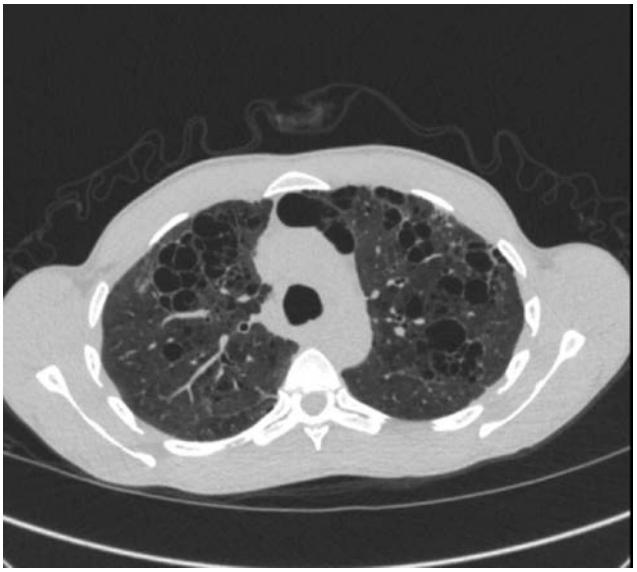

Figure 134-5 Numerous thinly walled cysts and diffuse interstitial ground-glass opacities in a patient with PCP.

Consolidation

Lung consolidation is infrequently encountered but may develop in more advanced disease, particularly in HIV-negative patients who are able to mount a more profound immune response. When present, consolidative changes with air bronchograms may be seen on

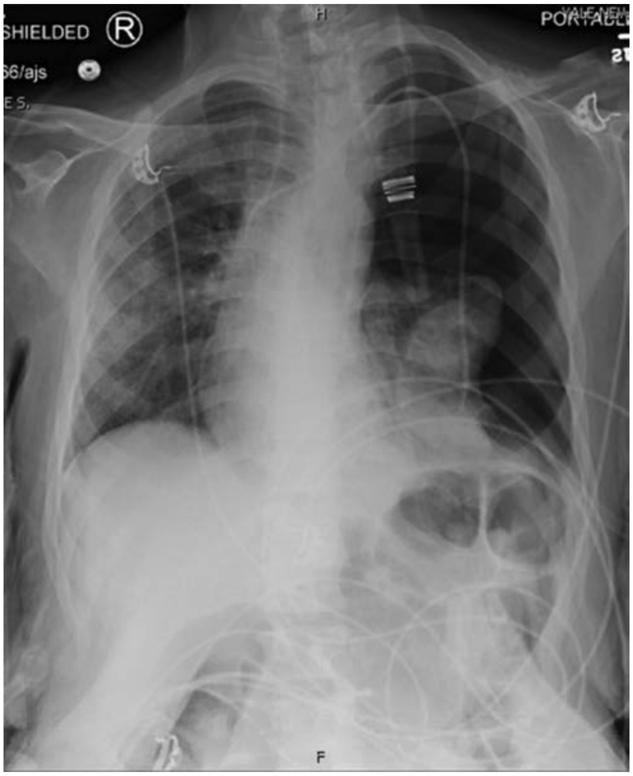

Figure 134-6 Large left pneumothorax with complete collapse of the lung and mediastinal shift toward the right with compression of the right lung in patient with PCP.

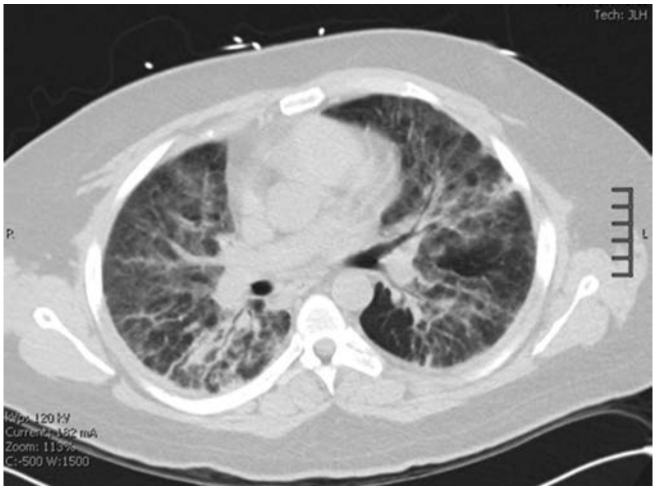

Figure 134-7 Diffuse lung disease affecting all five lobes with upper lobe–predominant ground-glass opacities and lower lobe–predominant peribronchovascular areas of consolidation in a patient with PCP.

both chest x-ray and chest CT, particularly in the setting of disease progression. Consolidations can be peribronchovascular, patchy, unilateral, or bilateral, and occur concurrently with interstitial infiltrates[57] (Fig. 134-7).

Pulmonary Nodules

PCP may rarely manifest as a predominantly nodular pattern on chest CT. This is thought to develop as a result of a granulomatous response to infection, known as granulomatous PCP.[64] Chest imaging in patients with granulomatous disease typically reveals solitary nodules, masses (3 cm or larger), or multiple randomly distributed nodules of varying sizes (Fig. 134-8). These findings may mimic lung carcinoma, metastatic disease, lymphoproliferative disorders, or other infectious etiologies frequently encountered in immunosuppressed patients such as fungal or mycobacterial disease. Granulomatous inflammation occurs in about 5% of cases and is more common in patients with hematologic malignancies than in those with AIDS.[57,64] Notably, diagnosis of granulomatous PCP is challenging since bronchoalveolar lavage may be negative due to encasement of the organism by granulomas.[64] Biopsy remains the cornerstone of diagnosis for this form of disease.

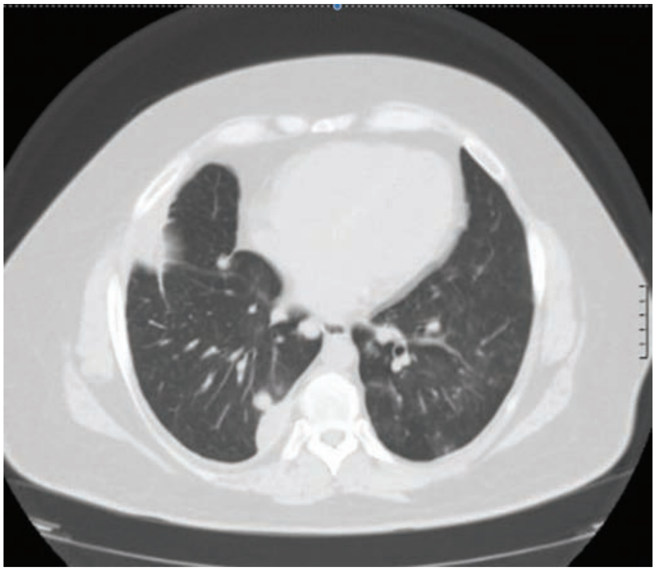

Figure 134-8 Scattered pulmonary nodules in a patient with biopsy-proven granulomatous PCP.

Other Imaging Findings

Pleural effusions may be encountered but are often secondary to a concurrent, alternative process. Patients with recurrent disease may develop residual interstitial fibrosis, with chronic interstitial markings or honeycombing on chest CT. Cavitation and calcification may infrequently occur with nodular disease.[60] However, these findings may be due to numerous alternative infectious and noninfectious etiologies in the immunocompromised host with multiple processes often occurring simultaneously.

LABORATORY FINDINGS

A number of nonspecific laboratory markers are frequently used to aid in the diagnosis of PCP. The most frequently utilized tests include CD4 and absolute lymphocyte counts, blood gas analysis, (1-3)-β-D-Glucan, lactate dehydrogenase (LDH), and other markers.

CD4 and Absolute Lymphocyte Counts

In PLWH, the incidence of PCP increases as the CD4 count decreases. Most cases occur with a CD4 count less than 200 cell/μL or a CD4 cell count percentage less than 14%. In fact, there is a 70% to 90% incidence of PCP in PLWH with a CD4 count of less than or equal to 200 cells/μL. In HIV-negative patients, low CD4 counts are also associated with an increased risk of developing PCP. In addition, low absolute lymphocyte counts have been associated with opportunistic infection in HIV-negative solid organ transplant (SOT) recipients. In one study, around 70% of SOT recipients with PCP had a CD4 count of less than or equal to 200 cells/μL and an absolute lymphocyte count of less than or equal to 500 cells/μL.[34,65] Similarly, both lymphopenia and decreased CD4 counts are risk factors for PCP in hematopoietic stem cell transplant (HSCT) recipients and patients with hematologic malignancies, autoimmune disorders, and solid tumors on chemotherapy.[35,66,67] Although CD4 and absolute lymphocyte counts may be useful to stratify the risk of PCP in HIV-negative patients, the relationship is not as clear as for PLWH, and lymphocyte counts are impacted by several other factors such as increased immunosuppression, CMV, or other viral coninfections.[68]

Blood Gas Analysis

In general, patients will have a PO_2 less than 75 mm Hg with a widened alveolar–arterial (A–a) oxygen gradient and a respiratory alkalosis.[69] More profound hypoxemia is often unmasked with exercise. In mild disease, the PO_2 is greater than 70 mm Hg with an A–a gradient less than 35 mm Hg while in severe disease, the PO_2 is less than 60 mm Hg with an A–a gradient greater than 45 mm Hg.[70]

(1,3)-β-D-Glucan

(1-3)-β-D-glucan is a cell wall component of *P. jirovecii* as well as many other pathogenic fungi and has gained acceptance as a useful but nonspecific marker of invasive fungal disease. Serum (1-3)-β-D-glucan values are almost always elevated in PCP but may also be elevated in a variety of other invasive fungal diseases such as candidiasis, aspergillosis, and fusariosis.[71] Other opportunistic fungi, like *Mucor* species and *Cryptococcus neoformans,* have little to no (1-3)-β-D-glucan in their cell walls and the assay has not been useful for these infections. Additionally, false-positive (1-3)-β-D-glucan results may occur after infusion of intravenous immune globulin, defibrotide, plasmalyte, and albumin, and with exposure to gauze.[72] Hemodialysis use with exposure to unmodified cellulose containing dialyzer membranes may also cause false positive (1-3)-β-D-glucan results.[73]

A number of studies have evaluated the utility of (1-3)-β-D-glucan for diagnosis of PCP. In general, the assay is very sensitive (>80%–100%) and has a high negative predictive value (>95%), indicating that patients with a negative (1-3)-β-D-glucan assay are very unlikely to have PCP.[74–81] These performance characteristics appear to be best in PLWH, likely because of increased organism burden in HIV/AIDS.[81] Because (1-3)-β-D-glucan can be elevated in other fungal infections, the specificity in an unselected population is relatively low. However, specificity is significantly increased in patients with a compatible clinical syndrome with higher (1-3)-β-D-glucan assay values. In a retrospective analysis of greater than 400 immunocompromised patients with a compatible clinical syndrome, a (1-3)-β-D-glucan value greater than 80 pg/mL yielded a specificity of 81% and positive predictive value (PPV) of 35%. In the same cohort, (1-3)-β-D-glucan values greater than 200 pg/mL yielded a specificity and PPV of 100%.[82] Thus, measurement of (1-3)-β-D-glucan is a very useful test, particularly for those in whom clinical suspicion for PCP is highest or those for whom a confirmatory bronchoscopy may be contraindicated since a positive (1-3)-β-D-glucan may serve as the basis for a probable diagnosis of PCP (see "Diagnosis: Consensus Definitions," below).

In small retrospective evaluations, persistently positive serum elevations of (1,3) β-D-glucan have been reported despite appropriate therapy and clinical improvement. The utility of this assay in determining prognosis or in therapeutic monitoring is unclear; however, it is generally accepted that serial measurements are unlikely to be clinically useful.[83,84]

■ LDH

Serum LDH is elevated (≥300 IU/mL) in almost all cases of PCP. Because LDH is a marker of underlying lung injury in PCP and other conditions, the degree of elevation correlates with underlying hypoxemia and may have prognostic value.[85] However, LDH may also be elevated in a variety of other pulmonary and extrapulmonary disorders, including malignancy, hemolysis, ischemia, and other infections such as toxoplasmosis and histoplasmosis among others.[86] Thus, LDH is a sensitive but nonspecific marker that should not be used in isolation for PCP diagnosis, particularly in the leukemic population where confounding etiologies of LDH elevation are more likely.

■ Additional Testing

There have been several case series suggesting that hypercalcemia is common in PCP, particularly among renal transplant recipients.[87,88] In one series, hypercalcemia (12.6 ± 1.6 mg/dl) was observed in 37% (18/49) of renal transplant recipients and regressed concomitantly with PCP treatment in all cases.[87] Hypercalcemia may precede the diagnosis of PCP in this cohort. While the etiology of hypercalcemia in this population is not entirely clear, it is thought to be associated with a 1 α-hydroxylase enzyme dependent mechanism, particularly in those with granulomatous disease. In the above study, serum levels of 1,25-dihydroxyvitamin D were elevated at the time of PCP diagnosis and decreased after PCP treatment while PTH serum levels increased, suggesting a granuloma-mediated mechanism for hypercalcemia.[87]

Another nonspecific indicator of lung injury in PCP is the angiotensin-converting enzyme (ACE) level, which can also be elevated by smoking and sarcoidosis, among other causes.[89] Krebs von den Lungen antigen (KL-6), a mucin-like glycoprotein expressed on pneumocytes and bronchiolar epithelial cells, can also be detected in the serum of patients with PCP, but once again is likely a nonspecific marker of pneumonitis in general.[85,90] These laboratory markers lack the specificity needed to be useful diagnostic tools in isolation but may be helpful adjuncts in the appropriate clinical setting.

DIAGNOSIS: HISTOPATHOLOGY, SPECIAL STAINS AND POLYMERASE CHAIN REACTION

The gold standard for the diagnosis of PCP remains the identification of characteristic organisms on examination of pulmonary specimens. Special stains must be used to highlight the morphology of *Pneumocystis* itself including cell wall stains, nuclear and cytoplasmic stains, and immunofluorescence stains. The presence of *Pneumocystis* in clinical specimens can also be detected using *Pneumocystis*-specific polymerase chain reaction (PCR) assays.

■ Lung Histopathology

The lung histopathology in the setting of PCP is characterized by typical features that have diagnostic value even when organisms are not initially seen. The hematoxylin and eosin stain, one of the most common stains used in the anatomic pathology laboratory, does not stain *Pneumocystis* organisms but instead reveals characteristic acellular foamy exudates. The infection is predominantly located in terminal alveoli with airspaces appearing honeycombed or vacuolated and filled with a foamy eosinophilic exudate that consists of organisms, surface glycoprotein, proteinaceous exudate from the lungs, and debris of macrophages and inflammatory cells while neutrophils and lymphocytes populate the alveolar interstitium. The disease can be patchy in distribution, making the characteristic histopathologic changes difficult to find. In malnourished children and HIV-negative adults, the interstitial component is more prominent. Using special stains on lung tissue, a large number of *Pneumocystis* organisms usually appear enmeshed with inflammatory cells within the alveolar exudate. Hyaline membrane formation may occur within alveoli as a result of denudement of the alveolar epithelium and deposition of cellular debris on the basement membrane.[91] This pattern of diffuse alveolar damage can be seen with oxygen toxicity, alveolar proteinosis, or acute respiratory distress syndrome (ARDS) and is not specific for either condition. A granulomatous response to *Pneumocystis* lung infection that includes nonnecrotizing or poorly necrotizing granulomas has been rarely described (Fig. 134-9A). These most often lack classic features of intra-alveolar foamy exudates and are more commonly seen among men with HIV/AIDS and hematopoietic or solid malignancies.[92]

■ Cell Wall Stains

Cell wall stains bind to components of the *Pneumocystis* cyst cell wall, but not those of other morphologic forms including the trophozoite. Since there are 10-fold more trophic forms than cystic forms in lung tissues during active infection, cell wall stains are insensitive for the diagnosis of PCP when the organism burden is low. This is especially true for HIV-negative immunocompromised individuals who harbor approximately 14 times fewer cysts per mL of BAL fluid than patients with HIV/AIDS.[47] Host cells including alveolar epithelial cells and macrophages are not stained, making detection of *Pneumocystis* organisms and stain interpretation easier. The methenamine silver stain (Grocott or Gomori variation) is one of the most commonly used in this category.[93,94] It stains *Pneumocystis* cysts black in a cup-shaped morphology against a green background (Fig. 134-9B). Focal thickenings in the *Pneumocystis* cyst cell walls stain more deeply and appear either as central black dots when the staining is confluent, or as thick "commas" or "parentheses" when the two distinct parallel areas are stained (Fig. 134-9C). Other cell wall stains include the toluidine blue, cresyl echt violet, and calcofluor stains. Toluidine blue and cresyl echt violet render a similar cyst appearance to the methenamine silver stain, but the organism color is purple against a light pink background. Calcofluor white stains the chitin in fungal cell walls and requires a fluorescence microscope for visualization of either apple-green fluorescent or blue–white cysts depending on the suppression filter used. Cell wall

stains are also useful to identify other pathogenic fungi including dimorphic fungi, molds, and yeasts. The sensitivity of cell wall stains for PCP is dependent on multiple factors that are discussed below and in Table 134-1.

■ Nuclear and Cytoplasmic Stains

Nuclear and cytoplasmic stains including the Giemsa, Wright-Giemsa, and Giemsa-like stains (such as the Diff-Quik) highlight the nuclei and cytoplasm of all *Pneumocystis* developmental stages. Trophozoite nuclei appear deep purple against a light blue cytoplasm, whereas the ghostly outlines of a cyst surrounds several (usually eight) internal deep purple–staining intracystic body nuclei. Modified Giemsa techniques have the advantage of faster turnaround time and lower cost and are usually preferred in clinical settings. Adequate interpretation of Giemsa-stained lung specimens requires experienced readers in order to distinguish between clumps of *Pneumocystis* organisms from the nuclei of host cells including alveolar and immune cells, which are larger in size. In the hands of an experienced laboratorian, Giemsa staining detects both cyst and trophozoite stages and so has increased sensitivity compared to cell wall stains. Additionally, since host cells are stained, demonstration of host alveolar macrophages can allow assessment of specimen adequacy. Nuclear and cytoplasmic stains will also identify other pulmonary fungal pathogens.

■ Immunofluorescence Stains

Fluorescein-conjugated monoclonal antibodies directed against *Pneumocystis* surface glycoproteins can be used to identify all *Pneumocystis* developmental stages in clinical specimens and have become a staple in the diagnosis of PCP. Both direct fluorescent antibody (DFA) and indirect fluorescent antibody (IFA) techniques are available.[95,96] DFA employs a chromophore-labelled antibody that binds directly to *Pneumocystis* antigens, while IFA consists of a two-step procedure in which a primary antibody that binds *Pneumocystis*-specific antigens is added, followed by layering with a secondary chromophore-labelled antibody that binds to the first antibody. Specimens are then examined under ultraviolet light for nuclear and/or cytoplasmic immunofluorescence. When the employed chromophore is fluorescein isothiocyanate, organisms and their surrounding matrix appear apple-green in color (Fig. 134-9D). Indirect immunofluorescence assays are more sensitive but less specific than DFA and require an additional staining step. Since commercially used IFA and DFA detect *Pneumocystis* cysts as well as the more abundant trophozoites, the sensitivity of immunologic techniques is superior to conventional staining and, when used on BAL fluid, approaches that of PCR testing. Immunofluorescent staining has the added advantage of allowing for visualization and quantification of the number of *Pneumocystis* organisms in a clinical specimen, enhancing the clinical specificity of the assay.

■ *Pneumocystis*-specific PCR Assays

Pneumocystis-specific nucleic acid amplification assays including PCR are highly sensitive for the detection of *Pneumocystis* in clinical specimens, superior even to immunofluorescence testing. A variety of commercial and laboratory-developed *Pneumocystis*-PCR assays are available, with the most sensitive employing either a multicopy gene target such as mitochondrial rRNA or major surface glycoprotein, or a nested PCR method that utilizes two amplification rounds.[32,97] Due to very low limits of detection, PCR assays maintain excellent performance in the setting of low organism burdens, such as with PCP in HIV-negative immunocompromised individuals. Conversely, because of high sensitivity, PCR assays suffer from decreased PPV for PCP because detection of low organism burdens in the absence of appropriate clinical, radiographic, and host factors more likely represents transient colonization rather than infection.[98] In studies performed among HIV-positive and HIV-negative individuals, the sensitivity of PCR was comparable to immunofluorescence testing but the PPV of PCR was lower once clinical and radiographic criteria were applied.[99,100] Combining serum (1-3)-β-D-glucan with PCR on respiratory samples can help discriminate *Pneumocystis* infection from colonization. In a study of high-risk oncology patients evaluated for PCP, a (1-3)-β-D-glucan level greater than or equal to 200 pg/mL with a positive PCR and a compatible clinical syndrome had a specificity of 100% and a PPV of 100% for proven or probable PCP versus a specificity of 97% and PPV of 75% for PCR alone.[82] Quantitative or semiquantitative PCR assays that provide a measure of organism burden may allow differentiation between colonization (a very low organism state) and infection (low to high organism state). The PCR assay cycle threshold (Ct, which is inversely proportional to fungal organism load) has been shown to be lowest for HIV-positive patients with confirmed PCP followed by HIV-negative patients with confirmed PCP and highest for patients with an alternative diagnosis, suggesting that Ct values may enhance clinical specificity and aid in differentiating infection from colonization.[95,101] Unfortunately, due to a lack of standardization, the performance of various commercially available PCR assays is variable and Ct thresholds cannot be extrapolated across different PCR assays, limiting the applicability of Ct cutoffs.[102] However, the Fungal PCR Initiative, a working group of the International Society for Human and Animal Mycology, is leading the effort to standardize *Pneumocystis* PCR assays. Recent multicenter studies have suggested that reverse transcriptase–qPCR assays targeting the mitochondrial small subunit gene provided the most precise and accurate Ct values and could serve as a basis for standardizing the *P. jirovecii* load.[103]

DIAGNOSIS: SPECIMEN TYPES

Several specimen types including induced sputum, bronchoalveolar lavage (BAL), oral washes, and lung biopsy can be examined in the diagnostic approach to PCP (Table 134-1). The sensitivity of different specimen types varies across the published literature and is reflective of heterogeneity in several important factors including (1) specimen adequacy, with suboptimal specimens commonly yielding false negative results, (2) the diagnostic method employed including cell wall or nuclear stains, immunofluorescence antibody testing, and PCR, (3) the reference method used as a comparator, (4) the population studied especially with regards to HIV-status, (5) the underlying burden of organisms, which is highest in profoundly lymphopenic HIV-positive persons and lowest in patients with mild disease and HIV-negative individuals, and (6) the use of prophylaxis or antecedent treatment.

■ Induced Sputum

Testing of induced sputum is a widely employed diagnostic tool for the diagnosis of PCP. Induced sputum samples are obtained by inhalation of aerosolized hypertonic saline using a nebulizer, after which specimens are most commonly stained with cell wall or nuclear stains to identify *Pneumocystis* organisms although immunofluorescence testing and PCR can be applied. The sensitivity of induced sputum for PCP ranges from 28% to 94% for people living with HIV and 0% to 88% for HIV-negative immunocompromised persons

TABLE 134-1 Sensitivity and Specificity of Various Specimen Types and Diagnostic Methods for PCP Diagnosis

	HIV-positive		HIV-negative[a]	
Specimen Type (Diagnostic Method)	**Sensitivity**	**Specificity[b]**	**Sensitivity**	**Specificity[b]**
Induced sputum (cell wall stain)	28%–94%[104,184–187]	100%[104,184–187]	35%–50%[188,189]	100%[188,189]
Induced sputum (immunofluorescence stain)	55%–89%[188,189]	98%–100%[99,188,189]	75%[190]	100%[190]
Induced sputum (PCR)	84%–98%[191]	71%–98%[99,191]	88%–100%[189,192]	81%–100%[189,192]
Oral wash (PCR)	44%–100%[110,193]	94%–100%[110,111,113–115,193]	100%[110,193]	100%[110,111,113–115,193]
Bronchoalveolar lavage (cell wall stain)	63%–100%[99,108]	100%[99,108]	46%–100%[108,189]	100%[108,189]
Bronchoalveolar lavage (immunofluorescence stain)	71%–100%[99]	100%[99]	16%–93%[100]	100%[100]
Bronchoalveolar lavage (PCR)	91%–100%[194,195]	83%–95%[194,195]	72%–100%[189,196,197]	90%–100%[189,196,197]
Transbronchial biopsy (cell wall stain)	43%–95%[116,118]	100%[116,118]	67%	100%[c]

[a] *Generally limited studies with small numbers of patients.*

[b] *Specificity definitions vary, with some studies reporting an analytical specificity and others clinical specificity, which distinguishes between colonization and infection.*

[c] *Unpublished data.*

when using cell wall staining but higher when immunofluorescence staining (55%–89%) or PCR (84%–98%) are used.[104] Although PCR specificity is often reported to be close to 100%, many studies report analytical sensitiivty (presence of *Pneumocystis* organisms) rather than clinical sensitivity (presence of *Pneumocystis* infection rather than just colonization). Induced sputum can be used as an initial screening method for PCP and, if negative, should be followed by invasive sampling with bronchoscopy and bronchoalveolar lavage, as repeat testing does not significantly increase diagnostic yield.[105] Expectorated sputum is generally considered inadequate for testing, especially since many patients with PCP do not have a productive cough. A retrospective comparison of expectorated and induced sputum yielded similar sensitivity of around 50% for both methods, although a direct fluorescent antibody screening was used rather than traditional staining.[106]

■ Bronchoalveolar Lavage

Testing of bronchoalveolar lavage (BAL) fluid for the presence of *Pneumocystis* organisms is considered the gold standard for PCP diagnosis and should be performed if noninvasive testing is negative in a patient with moderate to high pretest probability. Reported sensitivities for silver staining on BAL fluid have varied in published studies, ranging from 63% to 100% for HIV-positive patients and 46% to 100% for HIV-negative patients. Lavaging multiple lobes can increase the sensitivity and lavage should be performed from the upper lobes to improve the yield if diffuse disease is present.[107] However, BAL cell wall staining is generally considered inadequate for HIV-negative patients given the lower burden of infecting organisms and the potential for false negative results. In a recent study of 45 adult immunocompromised patients with proven or probable PCP by modified European Organization for Research and Treatment of Cancer (EORTC) criteria, the sensitivity of BAL silver staining was 100% in HIV positive versus 46% in HIV-negative patients.[108] Delayed or missed PCP diagnoses were seen in 3 cases in which BAL silver stain was negative. In HIV-negative patients, testing of BAL by PCR or immunofluorescence testing should be done if silver stain is negative. The sensitivity of BAL testing is higher when combined with immunofluorescence or PCR testing for both HIV-positive (71%–100% and 91%–100%, respectively) and HIV-negative patients (16%–93% and 72%–100%). The specificity of BAL immunofluorescence antibody testing may be higher, as PCR testing may confound infection with colonization.[99,100] Using a cycle threshold cutoff may improve the PPV of PCR assays.

■ Oral Wash

Testing of oral wash specimens using *Pneumocystis* PCR may be a more convenient and sensitive technique than induced sputum and a less invasive method than bronchoscopy.[109] Oral wash samples are obtained after patients gargle 50 mL of sterile saline for 10 to 30 s. The sensitivity of oral wash *Pneumocystis* PCR has varied in published studies, ranging from 54% to 100% for people living with HIV.[110–113] Among HIV-negative immunocompromised persons, the sensitivity was reported at 44% to 100%, but generalizability is limited by small numbers and use of different PCR assays.[114,115] As with other diagnostic methods, the clinical sensitivity of oral wash specimens is dependent on the underlying burden of organisms. In a study of 104 HIV-positive patients who underwent PCR and/or silver staining, only 50% of positive induced sputum specimens were positive by oral washes. Additionally, oral washes detected only 39% of patients with a low fungal burden compared to 63% of specimens with moderate to high load.[113] The results of this study are likely impacted by the use of cell wall staining, which is known to be an insensitive method when applied to oral specimens. When combined with a sensitive *Pneumocystis* PCR method, the sensitivity of oral washes is likely adequate for initial testing of HIV-positive patients with suspected PCP.

■ Lung Biopsy

The diagnosis of PCP can be made by examining lung biopsy specimens obtained through open thorax lung biopsies, a procedure rarely performed in the current era or during fiberoptic bronchoscopy. The most common diagnostic methods applied to lung biopsy tissue are cell wall or nuclear stains as part of general workup for fungal, parasitic, and bacterial organisms. The sensitivity of cell wall staining of transbronchial biopsy specimens ranges from 43% to 95% for HIV-positive patients and is likely lower for HIV-negative immunocompromised patients.[116] The added diagnostic value of transbronchial biopsy for the diagnosis of PCP when BAL testing is performed is unclear. In a study that included 95 patients with PCP for whom both transbronchial biopsy and BAL was performed, Giemsa staining of biopsy specimens identified only 2 cases of PCP that were missed by Giemsa-stained BAL alone.[117] However, in another study, the yield for PCP diagnosis was increased from 74% to 96% when examination of transbronchial biopsy specimens was combined with direct fluorescent antibody staining of BAL. In 26%, the diagnosis of PCP was obtained only by transbronchial biopsy.[118] The discrepant findings of these studies may be related to different methods applied to BAL and biopsy specimens as well as underlying population characteristics. In general, a lung biopsy specimen is no longer considered necessary for the diagnosis of PCP. In patients suspected of harboring multiple pathogens, obtaining a lung biopsy may be indicated. Bleeding complications after biopsy are common (25%) but rarely life-threatening if the coagulation parameters are normal.

DIAGNOSIS: CONSENSUS DEFINITIONS

Results of diagnostic tests for PCP must be taken within the context of all available host, clinical, radiographic, and microbiologic evidence in order to render an appropriate interpretation. In light of *Pneumocystis*' propensity to lead to transient pulmonary colonization without infection, highly sensitive tests, such as PCR, that may confound these two conditions should not be used as stand-alone evidence to diagnose PCP since doing so can lead to unnecessary antibiotic treatment and associated side effects with no clinical benefit. The EORTC and the Mycoses Study Group Education and Research Consortium (MSGERC) has established consensus definitions for the diagnosis of invasive fungal diseases. A recent update now includes criteria for pneumocystosis.[119] Although intended to guide clinical and epidemiologic studies, these definitions can be useful in a clinical context, especially when the diagnosis is in question. A proven diagnosis of PCP requires detection of the organism in BAL, sputum, or lung tissue using conventional or immunofluorescence staining while a probable diagnosis requires a constellation of factors including at least one host criterion (HIV/AIDS or other condition leading to a CD4 count of <200 cells/μL, T-cell depleting therapy, high-dose corticosteroids of ≥0.3 mg/kg for ≥2 weeks, or solid organ transplantation), clinical feature (includes respiratory symptoms and radiographic findings), and mycologic evidence [positive serum (1-3)-β-D-glucan on 2 consecutive serum samples or a positive *Pneumocystis* PCR assay on a respiratory tract specimen]. Cases that meet criteria for a host factor and a clinical feature but for which mycologic evidence has not been found are considered possible PCP, although a negative serum (1-3)-β-D-glucan has a very high negative predictive value for PCP and makes the diagnosis highly unlikely.[82] Notably, a positive *Pneumocystis* PCR test in the absence of host, clinical, and radiographic criteria and without detection of the organism using conventional or

TABLE 134-2 Treatment of *Pneumocystis jirovecii*[a]

Agent(s)(Route)[b]	Dose	Additional Considerations[b]
Trimethoprim-sulfamethoxazole (TMP-SMX) (IV/PO)	15–20 mg/kg/d TMP component	Treat through mild rash: reduce TMP or SMX by one-half; desensitize; first choice
Pentamidine isethionate (IV)	4 mg/kg/d 300 mg/d maximum	Nephrotoxicity, hypotension, electrolyte abnormalities, cardiac arrhythmias may be life threatening
Dapsone (PO) with TMP (PO/IV)	100 mg/d dapsone plus 5 mg/kg/d TMP	Methemoglobinemia, G6PD; *may* be tolerated in sulfadiazine allergy
Clindamycin (IV/PO) and primaquine	Clindamycin: PO 450–600 mg q6–8h; IV 900 mg q8h Primaquine 15–30 mg oral base qd	Methemoglobinemia, diarrhea (pyrimethamine for primaquine)
Atovaquone (PO) suspension	750 mg (PO) bid	Variable absorbance, improved with fatty food; rash, GI intolerance

IV, intravenous; PO, oral.

[b] *Based on clinical judgment of physician; some agents are not FDA-approved for this indication.*

immunofluorescence stains is consistent with neither proven, probable, nor possible PCP.

TREATMENT

If left untreated, PCP is almost uniformly fatal. Several effective therapeutic agents are available for the treatment of PCP (Table 134-2). Because of the potential for rapid clinical decline, treatment should be instituted as soon as PCP is considered based on epidemiologic, radiographic, and clinical grounds. Delay in therapy, more common among HIV-negative patients likely as a result of disease underrecognition, is a risk factor for increased mortality.[120,121] Based on several consensus guidelines, treatment should be continued for 21 days in HIV-positive individuals and for at least 14 days for HIV-negative immunocompromised patients.[122,123] Although data are lacking to guide duration of therapy for HIV-negative patients, practice recommendations for solid-organ transplant patients favor a 21-day course for PCP unless the clinical presentation and initial work support mild disease.[68] This is based on the significant risk of PCP recurrence among HIV-infected persons treated with shorter courses including those with lower burdens of disease.[124]

Clinical response to treatment initiation, including fever resolution and radiographic improvement, is variable but usually occurs sooner in HIV-negative (~5 days) than HIV-positive (~7–10 days) patients, likely because of lower burdens of organisms in the former group. Transient clinical deterioration may occur in the first 48 h after treatment initiation, especially in moderate to severe cases and among HIV-positive patients, likely as a consequence of a heightened inflammatory response to antigens released from dead organisms. A lack of response to therapy within a week is suggestive of another process, infectious or noninfectious, and should be investigated further with bronchoscopy and BAL and/or further chest imaging. Treatment options, many of which have been evaluated head-to-head in clinical trials (Table 134-3), include trimethoprim and sulfamethoxazole, trimethoprim and dapsone, pentamidine, clindamycin plus primaquine, and atovaquone. Combining medications does not lead to improved outcomes but increases the chance of adverse side effects.

■ Trimethoprim and Sulfamethoxazole

The treatment of choice in both HIV-positive and HIV-negative patients with PCP is the combination of the antifolate antibiotics trimethoprim and sulfamethoxazole (TMP-SMX). Sulfamethoxazole inhibits the folate biosynthetic enzyme dihydropteroate synthase (DHPS), which catalyzes the formation of dihydropteroate, but

TABLE 134-3 Head-to-head Comparisons of PCP Treatment Regimen Effectiveness and Side Effects Based on Clinical Trial Data[128–134]

Effectiveness/ Side Effects	TMP-SMX	Intravenous Pentamidine	Dapsone + TMP	Clindamycin/ Primaquine	Atovaquone
TMP-SMX	—	TMP-SMX more or equally effective	Equally effective	Equally effective	TMP-SMX more effective
Intravenous Pentamidine	Side effects less common with TMP-SMX	—	?	Clinda/prima more effective (salvage therapy)	Equally effective (mild disease)
Dapsone + TMP	Side effects less common with dapsone + TMP	?	—	Equally effective	?
Clindamycin/ primaquine	LFT elevation with TMP-SMX; hematologic toxicities with clinda/ prima	Sides effects less common with clinda/ prima	Side effects more common with clinda/prima	—	?
Atovaquone	Side effects less common with atovaquone	Side effects less common with atovaquone	?	?	—

TMP may be inactive against *Pneumocystis* based on data from animal models and the absence of polymorphisms in the gene coding for dihydrofolate reductase (the protein target of TMP), suggesting the absence of selective pressure in the presence of TMP.[125–127] Patients who have moderate to severe disease and those who cannot tolerate oral medications should receive the intravenous form. TMP-SMX benefits from wide availability, excellent tissue penetration, overall good tolerability, rapid clinical response (within 3–4 days), and both oral and intravenous formulations allowing for step-down therapy. In head-to-head randomized controlled trials, TMP-SMX was either more[128,129] or equally[130–132] effective compared with intravenous pentamidine for the treatment of PCP in HIV-positive[129,131,132] and HIV-negative[128] patients. These same trials showed that side effects were very common with both regimens (in up to 100% of patients) but TMP-SMX was less frequently associated with severe side effects including nephrotoxicity, hypotension, and hypoglycemia than pentamidine. Crossover trials also demonstrated that treatment changes from one agent to the other due to drug toxicity (in either direction) were associated with favorable outcomes, but changes made due to lack of treatment response were associated with high mortality.[130,131] The addition of pentamidine to TMP-SMX has not been associated with clinical benefit, and antagonism between these agents has been suggested in animal studies.[133] TMP-SMX was equally effective as clindamycin-primaquine and dapsone-trimethoprim for PCP in a multicenter randomized controlled trial. Elevation of liver enzymes to more than five times baseline levels was more common with TMP-SMX, while serious hematologic toxicities including neutropenia, anemia, thrombocytopenia, or methemoglobinemia occurred more frequently in the clindamycin-primaquine group.[134]

The recommended dose of TMP-SMX for the treatment of PCP is 15 to 20 mg/kg/day of the trimethoprim component divided in three to four daily doses for 21 days. In patients with moderate to severe disease, intravenous therapy is preferred up front; a switch to oral therapy can be done once there is clinical improvement. Patients with mild disease can be initiated on oral therapy, which benefits from a high oral bioavailability of approximately 85%. TMP-SMX requires dosing adjustment in the setting of renal impairment.

TMP-SMX is generally well tolerated, but minor toxicities including gastrointestinal disturbances, skin rashes (ranging from mild to severe), drug fever, hyperkalemia, and elevation of serum creatinine may occur (8% of HIV-negative patients).[135] Hyperkalemia results from blockade of distal nephron sodium channels by trimethoprim, whereas creatinine elevation is due to inhibition of creatinine secretion by trimethoprim, which leads to a reversible increase in serum creatinine independent of changes in glomerular filtration rates. The incidence of serious adverse events with TMP-SMX is greater in patients with HIV/AIDS (80% or more) and solid-organ and bone marrow transplant recipients. Treatment-limiting toxicities requiring a change of therapy (in ~50% of HIV/AIDS patients) usually occur around 7 to 10 days after treatment onset and include cytopenias, severe nausea and vomiting, hepatitis, pancreatitis, nephritis, metabolic acidosis, central nervous system manifestations, and severe drug allergy.[124,132,136,137] Solid-organ transplant recipients are particularly susceptible to nephrotoxicity (renal transplant recipients) and transaminase elevations (liver transplant recipients), while cytopenias are common in bone marrow transplant recipients. Dose reduction may reduce toxicities in some cases. Treatment continuation despite adverse side effects and with supportive management using antihistamines, antipyretics, corticosteroids, and/or therapeutic drug monitoring has been successful in published studies.[138]

In patients with immediate hypersensitivity reactions (type 1) or mild severe delayed hypersensitivity reactions (type 4) to TMP-SMX, oral and intravenous drug desensitization can be performed to allow use of the medication. When compared to re-introduction of TMP-SMX at a later date, desensitization resulted in fewer treatment discontinuations and adverse reactions in HIV-infected adult patients with a previous history of mild or moderate hypersensitivity to cotrimoxazole.[138]

■ Pentamidine

Pentamidine isethionate was first used to treat African trypanosomiasis due to *Trypanosoma gambiense* but also has activity against *Leishmania* and *Pneumocystis*. The drug interferes with microbial nucleic acids and protein synthesis, but the exact mechanism of action against *Pneumocystis* is unclear. Intravenous pentamidine is considered an alternative regimen for moderate to severe PCP, mainly due to the higher incidence of severe toxicities rather than decreased efficacy. Several randomized studies have shown that pentamidine is as or slightly less effective than TMP-SMX for PCP for HIV-positive and HIV-negative patients, although clinical response is faster with TMP-SMX.[128–132] Delayed response to pentamidine may be associated with high levels of extrapulmonary tissue drug deposition and a slow accumulation in the lungs over 5 to 7 days. Conversely, drug build-up in tissues and a long half-life of 12 days contribute to sustained elevated serum levels and a possible continued therapeutic effect after cessation of therapy. Pentamidine is associated with increased rates of failure and increased mortality when used as salvage therapy. In those cases, clindamycin and primaquine is preferred based on results from meta-analyses.[139] Pentamidine is administered intravenously at 4 mg/kg once a day via a slow infusion of 1 to 2 h. The inhaled form does not achieve sufficient systemic drug concentrations and should not be used for treatment.

Side effects are very common with intravenous pentamidine (in up to 80% of patients) and the main barrier to therapy. These include hypotension, tachycardia, arrhythmias (including torsade de pointes), hepatitis, pancreatitis, nephrotoxicity, hypo- and hyperglycemia, hypokalemia, hypomagnesemia, nausea and vomiting, facial flushing, pruritis, dysgeusia, hallucinations, and syncope. Side effects are exacerbated by intravenous administration and in the presence of decreased renal function. Hypoglycemia, which usually manifests early in the treatment course, is a result of damage to pancreatic β cells leading to increased release of insulin, whereas hyperglycemia, a later manifestation, results from destruction of pancreatic β cells and secondary diabetes mellitus.[140] Pentamidine should therefore be avoided in pancreas transplant recipients given the potential for islet cell necrosis. As with TMP-SMX, pentamidine induces hyperkalemia by interfering with urinary potassium excretion. Prolonged half-life contributes to lasting toxicities after cessation of therapy.

■ Clindamycin and Primaquine

The combination of clindamycin with primaquine is an alternative regimen for initial treatment of mild to moderate PCP. Although comparative data are lacking for the treatment of severe PCP, clindamycin and primaquine has advantages over intravenous pentamidine including good efficacy as primary and salvage therapy and a better side-effect profile. The mechanisms of action of clindamycin and primaquine are unknown but may be related to negative impacts on mitochondrial activity and nucleic acid synthesis, respectively.[141] Clindamycin and primaquine was equivalent to TMP-SMX and dapsone–TMP in one study, but toxicity was higher with the former regimen.[134] Clindamycin and primaquine is also the preferred regimen for salvage therapy in patients who do not respond to first-line treatment. In a meta-analysis of salvage therapy for PCP, 90% of patients who failed treatment with TMP-SMX or pentamidine or both had a good clinical response to clindamycin–primaquine.[142] In a more recent meta-analysis, the response rates for

TMP-SMX and clindamycin–primaquine as salvage therapy were 73% and 68% respectively, compared with 44% for pentamidine.[139] The recommended dose of clindamycin is 300–450 mg orally four times a day (or 600–900 mg IV every 6 to 8 h) and primaquine 15–30 mg of base daily. A G6PD level should always be checked prior to initiating primaquine, and the drug should be avoided in the setting of G6PD deficiency because of the potential for severe hemolysis. Common side effects include rash and gastrointestinal disturbances, including an increased risk of *Clostridioides difficile* diarrhea associated with clindamycin use.

Atovaquone

Atovaquone is an alternative treatment option for mild to moderate PCP. The mechanism of action against *Pneumocystis* is not clear but may be related to inhibition of cytochrome b within the electron transport chain, impairing metabolic function as is the case against *Plasmodium* species. Atovaquone is less effective than TMP-SMX for the initial treatment of PCP but leads to fewer treatment-limiting side effects.[143] In a randomized controlled trial of HIV-positive patients with mild to moderate PCP, the failure rate was greater with atovaquone compared with TMP-SMX (20% vs. 7%), and treatment with atovaquone was associated with a higher mortality rate at 4 weeks after treatment completion. Treatment-limiting toxicities requiring a change of therapy were more common with TMP-SMX.[144] Atovaquone showed similar efficacy to intravenous pentamidine for mild to moderate PCP treatment in patients with HIV, but treatment-limiting side effects were more common with pentamidine.[145] Taken together, these data highlight the main advantage of atovaquone, which is a favorable side-effect profile. Adverse reactions including rash, fever, diarrhea, and abnormal liver function tests typically are not severe enough to warrant discontinuation. The medication has a bitter taste that may impact adherence. Diarrhea and other gastrointestinal dysfunction may lead to poor absorption of atovaquone, decreased therapeutic drug levels, and worse clinical outcomes.[144] The recommended dose is 750 mg/5 mL via oral suspension, twice daily with food.

Dapsone and Trimethoprim

Dapsone is a folate synthesis inhibitor that can replace SMX and be combined with TMX for the treatment of mild to moderate disease. Dapsone plus TMX was equivalent to TMP-SMX and clindamycin–primaquine in terms of clinical efficacy and treatment limiting toxicities in a clinical trial. Serious hematologic disturbances and hepatitis were least common with the combination of dapsone and TMX.[134] As such, the regimen is an effective alternative treatment option. Although associated with fewer side effects than SMX, dapsone has a longer half-life (30 h), so toxicities may be longer-lasting. As with primaquine, dapsone can induce hemolysis in patients with G6PD deficiency. Other recognized hematologic toxicities include methemoglobinemia and anemia. Methemoglobinemia is thought to result from oxidation of the hemoglobin molecule by breakdown products of dapsone metabolism, leading to a decreased oxygen carrying capacity that can be fatal if methemoglobin levels exceed 70%.[146] Dapsone-induced methemoglobinemia may improve with discontinuation of therapy along with supportive treatment. Methylene blue can be administered for more severe cases and leads to conversion of methemoglobin to hemoglobin but should be avoided in the setting of G6PD deficiency where it may paradoxically induce hemolysis.[147] The recommended dose is dapsone (100 mg orally per day) in combination with oral TMP (15 mg/kg per day).

Adjunctive Therapies

Corticosteroids should be used in patients with moderate to severe infection, defined as having a Pa_{O_2} below 70 mm Hg at room air or an alveolar–arterial oxygen gradient of at least 35 mm Hg. Steroids have been demonstrated to reduce the likelihood of early deterioration of oxygenation, respiratory failure, need for mechanical ventilation, and death when combined with anti-*Pneumocystis* therapy for HIV-positive patients.[148] This is likely through blunting of an intensified immune response to dying organisms that would otherwise lead to uncontrolled lung damage. The evidence is less robust for HIV-negative immunocompromised patients. A meta-analysis showed no benefit of adjunctive corticosteroids in this population, but available studies were small and retrospective in nature.[149] Steroids continue to be recommended for non-HIV patients with PCP based on effectiveness in HIV-positive patients and expert opinion.[37] Steroids should ideally be administered prior to or within 72 h of initiation of PCP therapy, as corticosteroids initiated beyond 72 h have not been associated with any clinical benefit.[150,151] Corticosteroids may also be advantageous for patients with milder hypoxemia, but the benefit has not been confirmed. In HIV-positive patients with a high pretest probability for PCP and who meet oxygenation criteria, it is reasonable to initiate anti-PCP treatment with adjunctive steroids until the diagnosis is confirmed. The recommended regimen consists of oral prednisone in a dose of 40 mg twice daily for the first 5 days, followed by 40 mg daily for another 5 days, followed by 20 mg once daily for an additional 11 days for a total of 21 days of treatment. Other equivalent oral or intravenous steroid regimens including intravenous methylprednisolone can be used.[151] Tapering of steroids is thought to reduce the likelihood of a relapse of pulmonary inflammation.

In HIV-infected patients, treatment of the HIV infection with ART should be initiated within 2 weeks of the onset of PCP therapy. Randomized controlled trials have demonstrated that early initiation of ART in the setting of most opportunistic infections, including PCP, reduces the likelihood of AIDS progression and mortality by 50%.[152] For solid-organ transplant patients, a reduction of other immunosuppression is often pursued although such measures have not been evaluated in clinical trials. Colony-stimulating factors (CSF) including monocyte/macrophage (M-CSF) and granulocyte/macrophage (GM-CSF) lineages may enhance the clearance of *P. jiroveci* by alveolar macrophages without significantly increasing the inflammatory response in animal models, but there is little clinical evidence to support their use in PCP.[153]

Echinocandins

Echinocandins, antifungals most commonly used for the treatment of invasive candidiasis, have been increasingly explored as an experimental treatment option for *Pneumocystis* infection. Echinocandins exhibit antifungal activity via noncompetitive inhibition of the GSC1 subunit of the enzymatic complex involved in the synthesis of (1-3)-β-D-glucan, a key component of the *Pneumocystis* cell wall and much more abundant in cysts than trophozoites. Echinocandins have demonstrated activity against *Pneumocystis* in animal models, especially against cyst forms. Caspofungin rapidly depleted *Pneumocystis* cysts but not trophozoites in a murine model of infection, although it also appears to interfere with transport of surface glycoproteins and formation of tubular elements that are integral to the trophozoite stage.[13,154] Similarly, anidulafungin and rezafungin, a novel echinocandin, were effective against both *Pneumocystis* developmental stages.[155] Caspofungin was associated with increased survival in rodents with *Pneumocystis* infection. The question of lower efficacy against trophozoite forms has prompted evaluation of echinocandin in combination with other agents to enhance antifungal activity. Caspofungin plus TMP-SMX eradicated *Pneumocystis* from murine lungs, suggesting the possibility of synergism.[156] In human studies, echinocandin monotherapy or in combination with other agents has been effective for PCP as salvage therapy in HIV-positive[157] and HIV-negative patients,[158] but treatment failures have also been reported with monotherapy.[159,160] Based on these data, the 2016 6th European Conference on Infections in Leukemia (ECIL-6) guidelines cite the combination of TMP-SMX plus caspofungin as a salvage treatment option for HIV-negative patients with PCP but recommend against the use of echinocandin monotherapy.[123] Studies assessing the effectiveness of available and novel echinocandins for the treatment of PCP will be of continued interest given the considerable advantages afforded by this class of antifungals, which include minimal side effects and drug–drug interactions.[161] Glucan synthase inhibitors other than echinocandins, including the triterpenoid antifungal agent ibrexafungerp, have demonstrated in vitro and in vivo activity against *Pneumocystis* and represent a novel therapeutic class for the treatment of PCP.

■ Resistance

Drug resistance in *Pneumocystis* is difficult to ascertain because of the inability to perform in vitro susceptibility testing. However, the presence of mutations in key parts of the *Pneumocystis* genome, such as in genes that code for proteins targeted by antifungals, is suggestive of resistance. One such example is the DHPS gene, whose enzyme product is inhibited by SMX and dapsone. Sequencing of *P. jiroveci* clinical strains have revealed nonsynonymous polymorphisms in the DHPS gene that were much greater in frequency among patients who were exposed to sulfa drugs, suggesting that mutations arise from drug-induced selective pressure.[32,162] Mutations in DHPS have been associated with decreased survival and increased risk for treatment failure in patients receiving sulfa-based PCP therapy in some studies but not in others.[163–166] Taken together, these data suggest that long-term exposure to sulfa drugs may select for resistance but their impact on clinical outcomes appears to be limited. Although populations directly exposed to sulfa drugs are at increased risk for harboring *P. jiroveci* with mutated DHPS strains, adults with a first PCP episode in Chile had a high frequency of such mutations, suggesting that other factors such as interhuman transmission of resistant strains may impact resistance patterns.[167] *P. jiroveci* resistance to atovaquone is mediated by mutations in the cytochrome b gene within the mitochondrial genome. As with sulfa drugs, mutations to atovaquone are more common with prolonged drug exposure but because the rate of spontaneous mutations is significantly higher in the mitochondrial genome compared to the nucleus, resistance to atovaquone develops faster and mutated genes are much more diverse.[164]

PROPHYLAXIS

The use of appropriate prophylaxis is effective in preventing PCP. Several different prophylactic regimens exist, and strategies differ between persons living with HIV (PLWH) and HIV-negative immunosuppressed patients.

■ Indications

Below we consider indications for PCP prophylaxis in at-risk groups.

Persons Living with HIV

PCP is most likely to occur in patients who are not receiving antiretroviral therapy and whose CD4 cell counts are less than or equal to 200 cells/μL. Before widespread use of antimicrobial prophylaxis, PCP developed in 70% to 80% of people with AIDS.[168] Initiation of antiretroviral therapy to restore immune function is the most critical component of PCP prevention. However, PLWH benefit from PCP directed antimicrobial chemoprophylaxis until some measure of immune reconstitution is achieved. One of the earlier studies evaluating PCP prophylaxis showed that patients with CD4 counts less than 200 cells/μL who did not receive antimicrobial prophylaxis were nine times more likely to develop PCP than those who did receive prophylaxis.[25] Current guidelines recommend that primary PCP prophylaxis be administered to PLWH, including those on antiretroviral therapy, with CD4 counts less than 200 cells/μL or CD4 percentage less than 14%.[169] It may also be appropriate to administer prophylaxis when CD4 counts are between 200 and 250 cells/μL and frequent monitoring of CD4 counts is not feasible (i.e., at least every 3 months). After a course of therapy for PCP, patients with HIV/AIDS should continue to receive secondary prophylaxis to prevent infection recurrence. When patients achieve a CD4 count greater than or equal to 200 cells/μL or a CD4 count between 100 and 200 cells/μL with an undetectable HIV viral load for at least 6 months, secondary prophylaxis can be discontinued.[170] PCP occurring in an HIV-positive patient with a CD4 count greater than or equal to 200 cells/μL, especially while on antiretroviral therapy, suggests additional undefined qualitative cellular immune defects that predispose to disease recurrence. Therefore, such patients should be considered for lifelong prophylaxis unless a reversible host factor (such as chronic steroid use) can be identified and reversed.

HIV-negative Immunosuppressed Patients

Antimicrobial prophylaxis has been shown to be highly effective in preventing PCP in HIV-negative immunosuppressed hosts. In a meta-analysis of 12 randomized clinical trials involving HIV-negative immunosuppressed patients, TMP-SMX prophylaxis was associated with a 91% reduction in PCP occurrence and a significant reduction in PCP related mortality.[171] Prophylaxis is generally recommended for all solid-organ transplant recipients early after transplantation and lifelong for some organ types including lung allograft recipients. Risk of PCP is greatest within the first 6 months after transplant. With widespread use of prophylaxis and improved immunosuppressive regimens, the incidence of infection post-transplant has decreased to 0.3% to 2.5%.[37] Lung transplant recipients are particularly high risk. Routine prophylaxis is also recommended for all allogenic HSCT recipients and should be considered for select autologous HSCT recipients, particularly those with underlying lymphoma, myeloma, and leukemia, and in those who have received intensive treatment or conditioning regimens. In addition to transplant recipients, PCP prophylaxis is recommended for all patients with acute lymphoblastic leukemia as well as those receiving the monoclonal antibody alemtuzumab, phosphatidylinositol 3-kinsase inhibitors such as idelalisib, or a combination of radiotherapy and the alkylating agent temozolomide, and in patients with select primary immunodeficiencies such as idiopathic CD4 lymphopenia and severe combined immunodeficiency.[172]

One of the most common indications for PCP prophylaxis in HIV-negative hosts is the prolonged use of high-dose glucocorticoids. The 2020 Clinical Practice Guidelines for Prevention and Treatment of Cancer-Related Infections recommends consideration of PCP prophylaxis in cancer patients receiving the prednisone equivalent of 20 mg or more daily for 4 weeks.[172] Recent guidelines from the American Society of Transplantation suggest that PCP prophylaxis be considered in organ transplant recipients who receive the equivalent of 20 mg of prednisone daily for at least 2 weeks or for those receiving more intensive pulse-dose steroids for graft rejection.[37] While there are no guidelines for PCP prophylaxis for patients with rheumatologic diseases necessitating corticosteroid use, receipt of a prednisone equivalent of 20 mg daily for 4 weeks, especially in the setting of another cause of immunocompromise, is a generally accepted indication.

■ Regimens

Prophylactic regimens for PCP (Table 134-4) are summarized in the following sections.

TABLE 134-4 Regimens for *Pneumocystis jirovecii* Prophylaxis

Agent(s)	Dose	Common Adverse Reactions
Trimethoprim-sulfamethoxazole (TMP-SMX)	1 single-strength tablet daily *or* 1 double-strength tablet daily *or* 1 double-strength tablet 3 times weekly	Increased serum creatinine, hyperkalemia, bone marrow suppression[a]
Atovaquone oral suspension	1500 mg daily taken with food	Bitter taste, gastrointestinal upset
Pentamidine (inhaled)	300 mg monthly	Cough, bronchospasm, breakthrough disease particularly in upper lung zones
Dapsone	50 mg twice daily *or* 100 mg once daily	Hemolytic anemia in G6PD deficiency (required G6PD testing), methemoglobinemia, gastrointestinal upset

[a] *One double-strength tablet daily is preferred in patients with a coexisting indication for prophylaxis against toxoplasmosis (CD4 count < 100). Patients receiving treatment for toxoplasmosis with pyrimethamine/sulfadiazine do not require additional antimicrobial prophylaxis for PCP.*

Persons Living with HIV

TMP-SMX is the first-line agent for PCP prophylaxis. In a meta-analysis of 35 studies encompassing over 6500 patients, TMP-SMX was shown to be superior to both dapsone and aerosolized pentamidine.[173] TMP-SMX also provides protection against other clinically important pathogens including *Toxoplasma gondii*, *Listeria monocytogenes*, *Isosporabelli*, and susceptible bacteria, including some strains of *Streptococcus pneumoniae*, *Haemophilus influenzae*, community-acquired staphylococci, and some enteric Gram-negative rods. Infection with *Nocardia* spp., which are often sensitive to TMP-SMX, may also be prevented by prophylaxis. The optimal dosing strategy for PLWH differs based on the need to provide prophylaxis against toxoplasmosis. In patients with CD4 counts less than 100 cells/μL who are at high risk for toxoplasmosis, TMP-SMX is dosed at one double-strength tablet daily. In patients who do not require prophylaxis against toxoplasmosis, one single-strength tablet daily is the preferred dosing strategy, owing to better tolerability and equal efficacy compared with double-strength daily dosing. This is supported by a randomized trial that showed no difference in rates of PCP development in single-strength versus double-strength groups, but higher rates of adverse effects and treatment discontinuation in the double-strength group.[174] A dosing regimen consisting of one double-strength tablet three times weekly is an alternative option.

In patients who cannot tolerate TMP-SMX, alternative regimens include atovaquone 1500 mg daily, dapsone 50 mg twice daily or 100 mg daily, or aerosolized pentamidine. Aerosolized pentamidine is the least effective, and breakthrough disease has been well documented, particularly in the upper lung zones.[63,175] Dapsone and atovaquone have comparable efficacy, but both have drawbacks. In particular, dapsone may cause severe hemolytic anemia in patients who are G6PD deficient as well as methemoglobinemia. Patients must be screened for G6PD deficiency prior to initiation of therapy. Atovaquone may be prohibitively expensive and also causes gastrointestinal upset and must be taken with food.

HIV-negative Immunosuppressed Patients

Chemoprophylactic regimens are generally the same as those for PLWH. Guidelines recommend TMP-SMX as the first-line agent and can be administered as one single-strength tablet daily, one double-strength tablet daily, or one double-strength tablet three times weekly.[37,172] TMP-SMX–related adverse effects are particularly relevant in this population. In particular, TMP-SMX may cause mild bone marrow suppression. This tends to be overestimated but may be exacerbated when used in combination with other myelosuppressive agents. Some institutions avoid TMP-SMX in HSCT recipients at least through the time of engraftment, although data on this practice are limited. Trimethoprim also inhibits potassium and creatinine secretion, which can lead to elevations in serum potassium and creatinine, but this may not reflect a true decrease in glomerular filtration. This is reversible and more common during therapy than with prophylaxis. Some patients may not tolerate any dose of sulfa drugs, owing to significant rash (occasional Stevens–Johnson syndrome), hepatitis, interstitial nephritis, pancreatitis, or aseptic meningitis, although these complications are far less common. In the renal transplant population, thrice-weekly dosing with one double-strength tablet has been shown to limit these adverse effects and is likely as effective as daily dosing.[176,177]

Dapsone, atovaquone, and pentamidine remain second-line agents.[37,172] In a study of allogenic HSCT transplant recipients, breakthrough infection was shown to be more common in those receiving dapsone prophylaxis compared with TMP-SMX, although the dapsone dose used in this study may have been too low.[178] Atovaquone may provide comparable protection against PCP compared to TMP-SMX in this population, but it does not confer the same level of protection against other common opportunistic pathogens.[179]

■ Duration

The duration of PCP prophylaxis for HIV-infected persons and those with other immune-compromising disorders is considered below.

Persons Living with HIV

Primary prophylaxis may be safely discontinued in PLWH who have responded to antiretroviral therapy once CD4 counts are greater than 200 cells/μL for at least 3 months.[169] Primary prophylaxis can likely also be safely discontinued in patients with CD4 counts between 100 and 200 cells/μL if they are adherent to ART and have an undetectable viral load for a minimum of 3 to 6 months. This is supported by a large combined analysis of multiple European cohort studies that revealed an extremely low incidence of PCP in virologically suppressed patients with CD4 counts between 100 and 200 cells/μL.[180] Secondary prophylaxis can also be discontinued when either of these conditions are met.

HIV-negative Immunosuppressed Patients

Duration of chemoprophylaxis varies depending on the host and underlying immunosuppression. In general, PCP prophylaxis is recommended for all solid organ transplant recipients for at least 6 to 12 months post-transplant.[37] Lifelong prophylaxis is typically recommended for recipients of lung and small bowel transplants, and some cardiac, liver, and renal transplant programs also advocate for lifelong prophylaxis.[181] If immune suppression cannot be reduced after a course of treatment for PCP, prophylaxis should be maintained indefinitely. For recipients of allogeneic HSCT, prophylaxis is typically continued for at least 6 months and potentially longer if immunosuppression is unable to be tapered.[172] In both solid-organ and HSCT recipients, reinstitution of prophylaxis should be considered with increases in immune suppression, particularly pulse corticosteroids or antilymphocyte antibody therapies for treatment of organ rejection or graft-versus-host disease. For patients with acute lymphoblastic leukemia and for those treated with temozolomide or phosphatidylinositol 3-kinsase inhibitors, prophylaxis is generally continued for the duration of active therapy. In patients receiving alemtuzumab, prophylaxis is recommended for at least 2 months after completion of therapy, and until CD4 cell counts are greater than 200.[172] In patients receiving high-dose corticosteroids, prophylaxis should be continued at least through the completion of the steroid taper and/or for up to 6 weeks after cessation of therapy.[182]

Data regarding duration of prophylaxis in HIV-positive transplant recipients are relatively limited. In some instances, PCP prophylaxis is prescribed lifelong. However, in a recent study of 122 HIV-positive kidney transplant recipients, no patients developed PCP after prophylaxis was stopped at 6 months, suggesting that a 6-month regimen of PCP prophylaxis may be sufficient among HIV-positive recipients, similar to those without HIV.[183]

CONCLUSIONS

Pneumocystis jiroveci is an opportunistic pathogen that produces a clinical syndrome ranging from asymptomatic infection to subacute and acute interstitial pneumonia in susceptible hosts. While the syndrome of PCP came to worldwide prominence during the HIV/AIDS epidemic in the 1980s, the incidence of PCP is currently highest in HIV-negative immunocompromised patients owing to improvements in HIV treatments and increases in the number of HIV-negative patients receiving heavily immunosuppressive therapies. Established consensus definitions have recently been developed, with diagnosis requiring a combination of clinical, radiologic, and mycologic evidence. The treatment of choice in both HIV-positive and HIV-negative immunosuppressed patients is TMP-SMX, which has also proven to be a highly effective regimen for prevention of disease in vulnerable hosts.

CHAPTER 135

Protozoan Infections of the Thorax

Louise C. Ivers
Edward T. Ryan

INTRODUCTION

Protozoan infections of the thorax are generally quite rare. Other infectious and noninfectious processes can mimic their presentation, and the clinician needs to be aware of the possibility of these more rare pathogens, especially in endemic regions. Diagnostics can be more challenging and may necessitate more invasive procedures to obtain the diagnosis. Treatment is not always straightforward and may require surgical intervention with some infections.

AMEBIASIS: *ENTAMOEBA HISTOLYTICA*

Entamoeba histolytica is a protozoan infection of humans that is found worldwide and is globally responsible for tens of thosands of deaths annually. It is endemic in most temperate and tropical areas of the world, particularly in areas with poor socioeconomic development and limited sanitation. Serologic evidence of prior or current infection with *E. histolytica* is present in 5% to 50% of individuals in impoverished populations. *E. histolytica* is infectious in the cyst form. Transmission usually occurs as a result of contamination of food or water, but may also occur by means of oral–anal contact. Infection is common in developing countries. In Europe and the United States, infection is most commonly seen in individuals who have lived in endemic areas of the world. Institutionalized individuals are also at increased risk of infection. Sexually active men who have sex with men are also at increased risk of infection. There does not appear to be an increased risk of invasive disease in persons with HIV infection.

A morphologically identical but nonpathogenic protozoan, *Entamoeba dispar*, also infects the human gastrointestinal tract. It can be distinguished from *E. histolytica* by antigenic, genetic, and immunologic methods. Infection is 10 times more prevalent with *E. dispar* than with *E. histolytica*; however, the former does not cause invasive disease. Many older epidemiologic studies relied on microscopic diagnosis alone, and inadvertently incorporated both pathogenic and nonpathogenic species in estimates of prevalence of infection.

E. histolytica has a simple life cycle involving an infectious cyst and an ameboid trophozoite phase. Cysts may survive in the external environment for several weeks to months, especially in damp conditions and temperatures between −5°C and 40°C. After ingestion by humans, cysts excyst in the small intestine, each forming eight daughter trophozoites. These motile trophozoites can adhere to the intestinal wall; it is in this form that they may invade the mucosa, causing symptomatic invasive disease. In the colon, trophozoites encyst to complete the life cycle and are excreted. Trophozoites do not survive outside the human host.

■ Clinical Manifestations

The incubation period for intestinal amebiasis is usually 1 to 4 weeks, but ranges from a few days to months. Infection with *E. histolytica* is asymptomatic in up to 90% of cases, but may cause a range of gastrointestinal symptoms from mild diarrhea to severe colitis with bloody diarrhea. Symptoms result from penetration of the trophozoites through the mucosal barrier with invasion of the colon wall. In the absence of frank blood, stool is usually positive for occult blood. Fever is present in less than half of cases. Fecal leukocytosis is usually less marked than in bacterial colitis. Rarely, progression of invasive intestinal disease may lead to severe colitis and bowel perforation. On occasion, granulation tissue formation surrounding a localized area of invasive disease may form an inflammatory mass (an "ameboma") and manifest as a tender abdominal mass.

Extraintestinal disease most commonly occurs in the liver, and manifests as a liver "abscess." In this instance, trophozoites migrate to the liver via the portal veins, and infection results in inflammation, necrosis, and ultimately a fluid collection. The collection is often referred to as an abscess; however, it does not contain polymorphonuclear cells like a true abscess, but only cellular debris. Eighty percent of amebic hepatic abscesses are solitary, and 80% occur in the right lobe of the liver. Extraintestinal disease may present years after residence in an endemic area and should be considered in all patients with an appropriate travel history and suggestive symptoms. Liver abscesses occur more frequently in men than women, and usually in the age range of 18 to 50 years.

Thoracic manifestations of *E. histolytica* infection are rare; they have been reported in 2% to 3% of cases of invasive amebiasis. They can be considered chiefly as either pleuropulmonary or pericardial. A case of *E. histolytica* osteomyelitis of the rib has been reported, as has a case of pulmonary amebiasis presenting as superior vena cava syndrome.[1]

■ Pleuropulmonary Disease

Amebic pulmonary disease may occur by a number of mechanisms.[1–3] It most often occurs as the result of a concomitant liver abscess. The abscess may result in an ipsilateral sympathetic pleural effusion that does not require specific therapy. A liver abscess may alternatively rupture through the diaphragm into the pleural space, causing respiratory distress, empyema, and subsequent parenchymal lung abscesses (Figs. 135-1 to 135-3). Pulmonary parenchymal disease in the form of lung abscesses and consolidation less often occurs in the absence of hepatic disease, but may occur if there has been hematogenous spread of trophozoites to the lung or infectious thrombophlebitis.[4]

Most patients with extraintestinal amebiasis have not had symptomatic intestinal disease, so the absence of preceding gastrointestinal symptoms does not exclude the diagnosis. Patients with liver abscess often present with insidious onset of fever, right upper quadrant pain, and hepatic tenderness on palpation. Pleuritis, respiratory symptoms such as cough, dyspnea, and/or physical examination consistent with pleural effusion further suggest involvement of the pleuropulmonary system. Sputum production may range from scant to copious, and sputum may contain purulent material, particularly if a hepatobronchial fistula has developed. Classically, the purulent material of amebic abscess is reddish "anchovy paste." Jaundice is uncommon. Leukocytosis may be present, but eosinophilia is not a feature of the disease.

■ Pericardial Disease

Pericardial disease can result from either sterile inflammation of the pericardium as a result of a contiguous liver abscess in the left lobe of the liver, or may be a purulent infection as a result of rupture of a hepatic amebic abscess into the pericardial space (Fig. 135-4). Chest pain, pericardial friction rub, and symptoms and signs of pericarditis may be presenting features. Presentation may be acute and severe, with symptoms and signs of pericardial tamponade.[5]

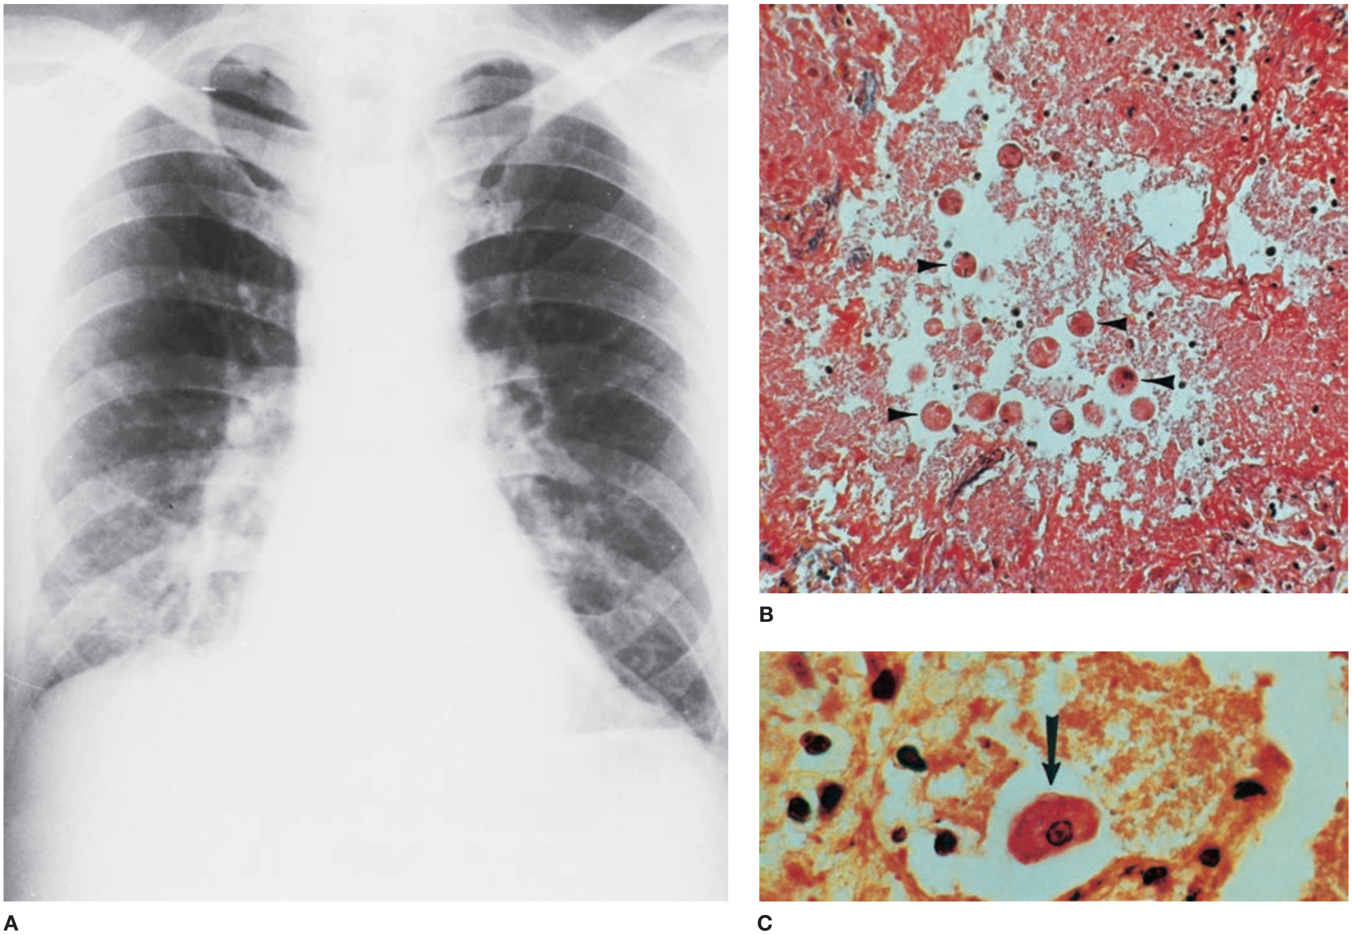

Figure 135-1 *Entamoeba histolytica* involving the right lung after rupture of a hepatic abscess through the right hemidiaphragm. **A.** Chest radiograph shows elevated right hemidiaphragm, right lower lobe infiltrate, and effusion. **B.** Alveolar spaces are filled with amebae *(arrowheads)*. (Iron hematoxylin stain, ×300). **C.** Trophozoite *(arrow)* and necrotic debris. *(**A.** Reproduced with permission from Armed Forces Institute of Pathology [AFIP]; **B.** Reproduced with permission from Dr. Y. Gutierrez.)*

Trophozoites of *E. histolytica* were obtained at bronchoalveolar lavage. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

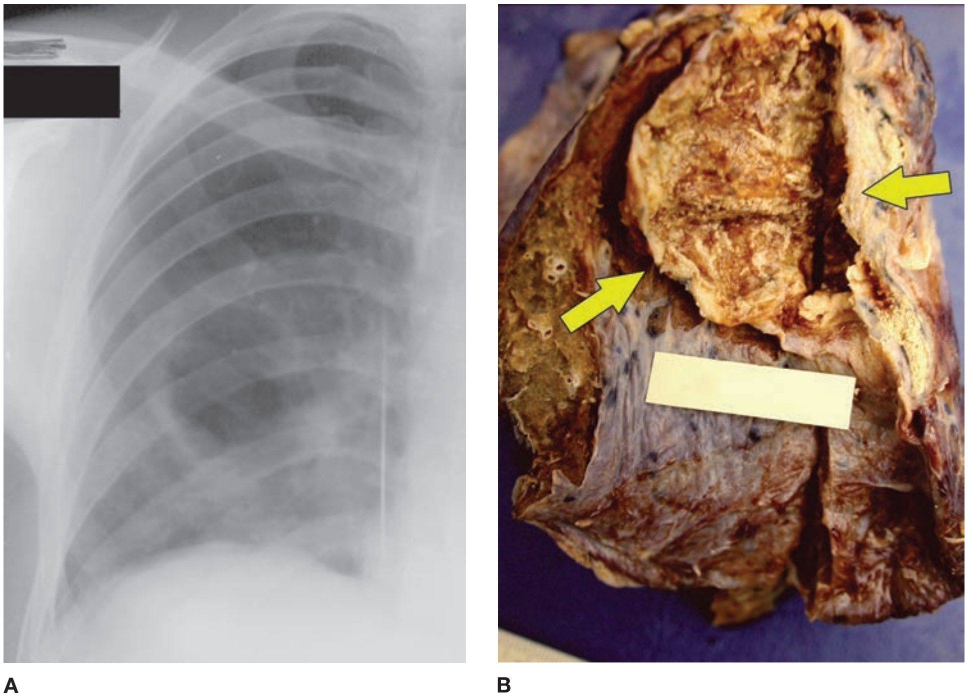

Figure 135-3 Right-sided amebic pneumonia in a 35-year-old man with a hepatic abscess. **A.** Chest radiograph shows elevation of the right hemidiaphragm and right-sided basal consolidation with cavitation. **B.** Photograph of the gross specimen demonstrates an irregular cavitary lesion *(arrows)*. Anchovy sauce content and trophozoites of *E. histolytica* (not shown) were found on the lesion wall. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

■ Diagnosis of Pleuropulmonary and Pericardial Disease

Stool microscopy may reveal the presence of *E. histolytica* trophozoites or cysts, but microscopy is neither a sensitive nor a specific method for the diagnosis of amebiasis. Microscopy is unable to distinguish *E. histolytica* from nonpathogenic *E. dispar*, and extraintestinal disease is associated with presence of the pathogen in stool in only a minority of cases. Stool may be concentrated and stained with iodine to evaluate for the presence of cysts. Trophozoites are best seen on a fresh smear with iron hematoxylin and trichrome stain. Microscopy of abscess fluid occasionally may

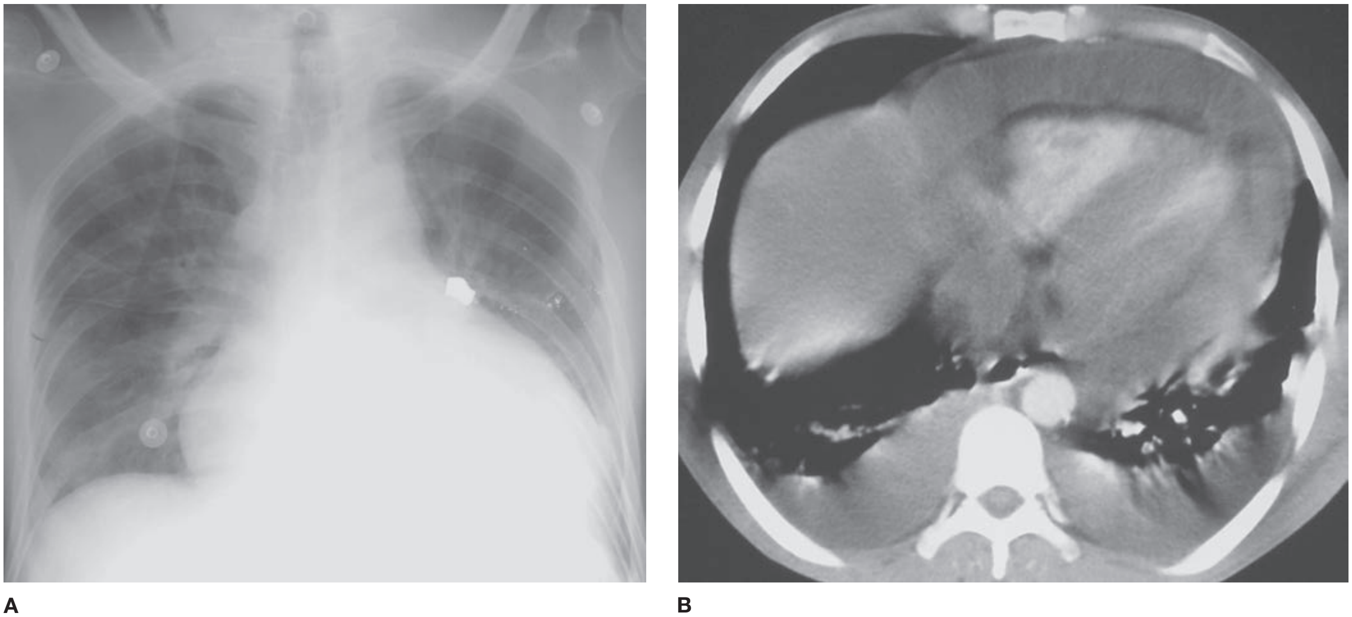

Figure 135-4 Amebic pericardial tamponade in a 27-year-old man with an abscess of the left hepatic lobe. The patient presented with pulsus paradoxus, fever, and chills. **A.** Chest radiograph shows enlargement of the cardiac silhouette. **B.** Chest CT scan shows extensive pericardial effusion that resulted from rupture of a left hepatic lobe abscess (not shown) into the pericardial space. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

reveal presence of trophozoites. Diagnosis of extraintestinal disease is best made by a combination of microscopic examination of samples, antigen detection, and serology tests.

Antigen Detection

Antigen detection methods detect *E. histolytica*. These tests are able to distinguish *E. dispar* from *E. histolytica*. Stool antigen tests are over 95% sensitive and specific for the diagnosis of intestinal disease. Antigen detection assays are also highly sensitive and specific when applied to abscess fluid.

Serology

Most patients infected with *E. histolytica*, but not *E. dispar*, develop a serum antibody response. Amebic serology is positive in over 90% of patients with extraintestinal disease. Serologic analysis may be negative in early infection. The presence of IgG antibodies does not always indicate active disease; IgG may persist for many years after active infection.

Treatment

Metronidazole or tinidazole is effective in the treatment of individuals with intestinal and extraintestinal amebiasis. To prevent a relapse, a luminal agent such as iodoquinol or paromomycin also should be administered. Sympathetic pleural effusions do not need specific therapy, other than treatment of the underlying liver abscess. Amebic empyema and amebic pericarditis are best treated with aspiration or percutaneous drainage, in combination with administration of antiamebic microbial therapy.

FREE-LIVING AMEBA: ACANTHAMOEBA

Free-living amebae are rarely associated with human infection; however, when infection does occur, disease tends to be progressive and difficult to treat.

Acanthamoeba spp. are ubiquitous, and have been isolated from a wide variety of locations, including the nasal passages of healthy adults, water sources, soil, and contact lens fluid. Infection in humans usually manifests as either keratitis or systemic disease. Systemic disease usually involves the central nervous system, manifesting as granulomatous amebic encephalitis. Amebic infection of skin also has been reported.

Clinical Features

Acanthamoeba sp. keratitis is usually a disease of healthy individuals, often contact lens wearers. Infection is thought to result from direct deposition of ameba into the eye. In contrast, systemic disease results from hematogenous dissemination of ameba, which are thought to first enter the human host via the respiratory tract or skin. Systemic disease is primarily a disease of immunocompromised or debilitated persons, including individuals with acquired immunodeficiency syndrome (AIDS), and those who have undergone bone marrow transplantation, organ transplantation, or are otherwise immunosuppressed. Pulmonary nodular infiltrates and pneumonitis have been reported in cases of systemic disease.[6]

Diagnosis

Diagnosis of systemic acanthamebiasis is usually made late in the clinical course, and unfortunately, very often at autopsy. Evaluation of cerebrospinal fluid from individuals with granulomatous amebic meningoencephalitis may disclose hypoglycorrhachia and elevated protein, but amebae are not usually seen. Evaluation of biopsies of lesions of skin or brain usually provides the definitive diagnosis. *Acanthamoeba* spp. can be identified on histopathology, and may be cultured on nutrient agar overlaid with *Escherichia coli*. Radiographic imaging of the central nervous system is often helpful.

Treatment

No single drug is effective against systemic *Acanthamoeba* spp. infection. Combinations of treatment with amphotericin B, miltefosine, azithromycin, voriconazole, posaconazole, isavuconazole, fluconazole, 5-fluorocytosine, pentamidine, metronidazole, rifampicin, sulfadiazine and other agents have been attempted, with success in some cases and failure in other cases that used similar regimens. Most individuals with systemic amebiasis do not survive, regardless of therapy. Individuals with acanthamebic keratitis are usually treated topically and may require corneal grafting.

SYSTEMIC COCCIDIOSIS: TOXOPLASMOSIS

Toxoplasmosis is caused by *Toxoplasma gondii*. Asymptomatic disease is common. Symptomatic disease usually occurs in persons with suppressed cell-mediated immunity and infants born with congenital infection.

Epidemiology and Life Cycle

Understanding the life cycle of *T. gondii* is important in understanding the disease process. The parasite is found worldwide. It has both sexual and asexual stages, the latter being the pathogenic stage in humans and other animals. Cats are the definitive host, and in the feline, oocysts develop after an intestinal intraepithelial sexual cycle. Oocysts are then passed in cat feces, and after 2 to 3 days become infectious. They may persist in soil. If ingested by humans or other animals (sheep, pigs, rodents, or cats), oocysts produce rapidly dividing tachyzoites. Tachyzoites invade varying cell types and result in cell death and tissue necrosis. Eventually the host immune response curtails this process, and tachyzoites give rise to slowly dividing bradyzoites, which encyst and persist indefinitely in host tissues. Bradyzoites are infectious if ingested, giving rise to tachyzoites in the new host. Bradyzoites may also revert to tachyzoites if a host becomes immunocompromised, leading to “reactivation” of disease. Humans and other animals may be infected, not only by ingestion of oocysts, but also by ingestion of tissue cysts, such as following the consumption of undercooked infected meat. Toxoplasma infection may also be acquired by transplacental passage of tachyzoites, resulting in congenital infection, or by organ transplantation.

Serologic studies demonstrate a wide geographic variation in prevalence of infection between 10% and 90%. In the United States, rates range from 3% in Denver, Colorado, to 17% in Massachusetts, and 30% in Birmingham, Alabama.

Clinical Features

Infection may be primary or due to reactivation. After ingestion of infectious oocysts or tissue cysts, tachyzoites disseminate and invade organs, replicating intracellularly. Acute infection may result in tachyzoites being found in all organs, especially muscle, lymphatic tissue, and the central nervous system. Primary infection may be subclinical or asymptomatic. If symptomatic, the most common manifestations of acute disease include fever, painless lymphadenopathy, and a mononucleosis-like syndrome. More rarely pneumonitis, myocarditis, and myositis may occur.

Congenital infection is usually the result of primary infection in the mother, with transplacental passage of tachyzoites resulting in infection of the fetus. Infected infants may be symptomatic at birth, or may have hepatosplenomegaly, pneumonitis, myocarditis, rash, or jaundice. Congenitally infected children may be asymptomatic initially, but may subsequently develop central nervous system or ocular manifestations.

Reactivation disease occurs in persons who are immunocompromised, particularly those with deficiency in cell-mediated immunity. Patients with organ or bone marrow transplants or who have HIV infection and CD4 cell counts less than 100 cells/mm^3

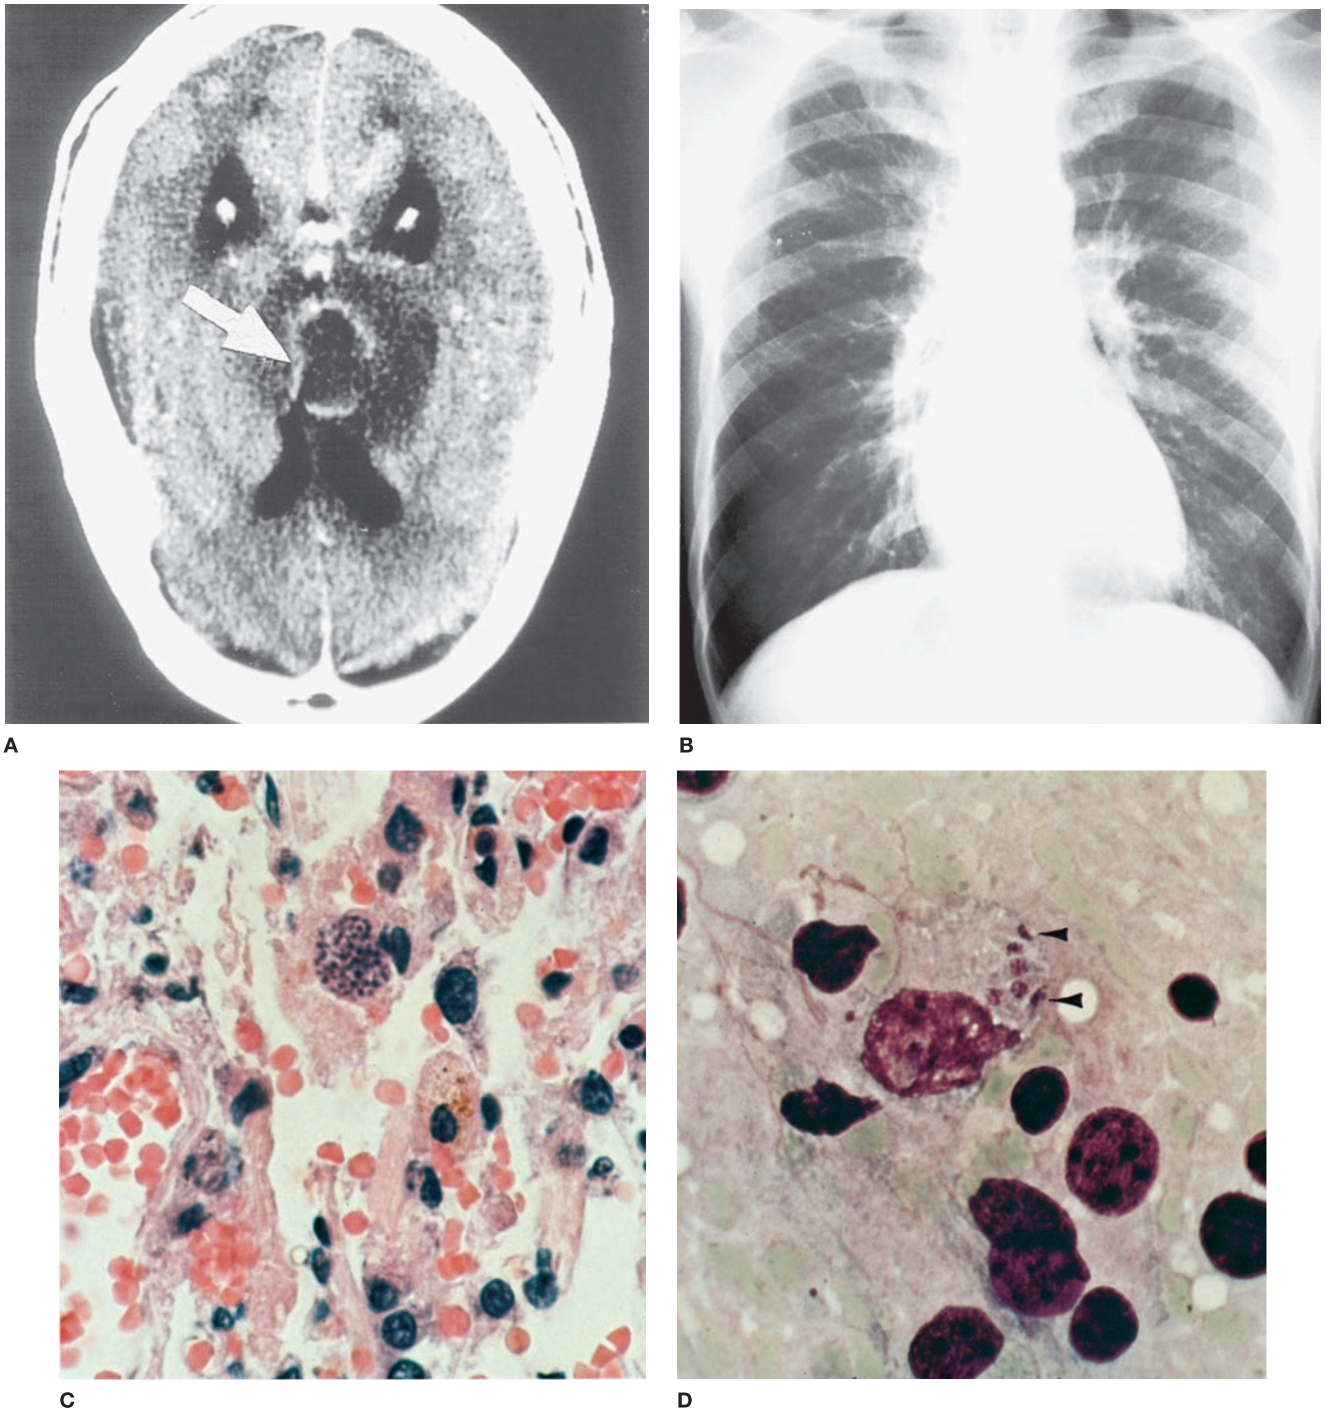

Figure 135-5 *Toxoplasma gondii* in the brain and lung of a patient with AIDS. **A.** Brain CT scan shows *Toxoplasma* abscess as a contrast-enhancing lesion *(arrow)*. **B.** Chest radiography. Diffuse bilateral infiltrates and hilar adenopathy. **C.** Lung biopsy shows *Toxoplasma* forms (arrow, cyst, hematoxylin & eosin stain, ×100). **D.** Impression smear of brain biopsy shows five intracellular tachyzoite (trophozoite) forms (*arrowheads*; Giemsa stain ×1500). *(C and D are Reproduced with permission from Dr. Y. Gutierrez.)*

are at particular risk of life-threatening disease. For those with HIV, although primary infection may occur in these individuals, reactivation disease is most common. Reactivation disease may be prevented in those at particular risk with the prophylactic use of trimethoprim–sulfamethoxazole. Necrotizing central nervous system disease is the most common manifestation of reactivation toxoplasmosis in AIDS patients. Affected individuals usually present with altered mental status, fever, headache, and clinical findings suggestive of focal CNS disease, and neuroimaging often reveals multifocal, ring-enhancing lesions.

■ Pulmonary Disease

Pulmonary involvement in toxoplasmosis is common, and is usually reported in patients with AIDS or in individuals who have undergone bone marrow or solid-organ transplantation (Fig. 135-5).[7–9]

Shortness of breath and cough are the most common presenting symptoms of pulmonary involvement during toxoplasmosis. In one review, immunocompetent patients with toxoplasmic pneumonitis were more likely than immunocompromised individuals to have evidence of hepatosplenomegaly at presentation, but clinical findings were otherwise similar. Bilateral interstitial pulmonary infiltrates are most often evident in radiography; however, a variety of other findings, from discrete pulmonary opacities to cavitary disease, also have been described. Severe disease or the acute respiratory distress syndrome (ARDS) may develop. *T. gondii* organisms can invade myocytes, and during acute or reactivation disease, myocarditis may occur and may be severe.

■ Diagnosis

In primary toxoplasmosis, the differential diagnosis is broad, but IgM-specific antibodies will usually be present. During reactivation of toxoplasmosis, IgM and IgG antitoxoplasma antibodies are usually present in serum. Absence of antitoxoplasma IgG antibodies makes the diagnosis of reactivation toxoplasmosis unlikely, but the presence of the antibody itself does not differentiate between latent and active diseases.

Biopsy can confirm the diagnosis. Polymerase chain reaction (PCR) analysis of blood, tissue samples, or cerebrospinal fluid is sensitive, and PCR analysis of amniotic fluid is particularly helpful in the antenatal diagnosis of congenital infection. PCR has been used to detect toxoplasma in sputum specimens, but the sensitivity of this method for diagnosing pulmonary toxoplasmosis has not yet been determined. In pulmonary disease, microscopic or molecular analysis of bronchoalveolar lavage fluid or open lung biopsy may be required for confirmation of the diagnosis.[10]

■ Treatment

Except in the case of pregnant women or individuals with severe or persistent symptoms, primary toxoplasmosis in immunocompetent individuals usually does not require treatment. Reactivation disease in immunocompromised individuals is usually treated for the duration of the period of immunosuppression, as therapy does not fully eradicate the parasite; this is often done with a combination of treatment followed by ongoing prophylaxis. Standard therapy is pyrimethamine and a sulfonamide, usually sulfadiazine. Leucovorin is added to overcome the bone marrow suppressive effects of pyrimethamine. Clindamycin or atovaquone may be used as an alternative in those intolerant of sulfonamides. Trimethoprim-sulfamethoxazole may also be used if sulfadiazine/pyrimethamine is not available. After acute disease has been controlled, secondary suppressive therapy should be continued for the duration of immunosuppression to prevent relapse. Unfortunately, mortality in immunocompromised patients with *Toxoplasma* pneumonia diagnosed antemortem has been as high as 40%.

INTESTINAL COCCIDIOSIS: CRYPTOSPORIDIOSIS

Cryptosporidium spp. *(C. hominis/parvum* and *C. muris)* are intracellular protozoans that mainly cause intestinal pathology (Fig. 135-6). Disease may occur in immunocompetent hosts but is more common and severe in immunocompromised individuals, particularly in patients with AIDS, in whom cryptosporidiosis may result in severe and persistent diarrhea. The organism also causes infection in a variety of animals, and fecal contamination of water or food is a common source of infection in humans, although person-to-person transmission also occurs.

The life cycle of *Cryptosporidium* spp. begins when the infectious oocyst is ingested. These organisms, which are 4 to 5 μm in diameter, may remain viable in the environment for months. After ingestion, they excyst in the small intestine and release four motile sporozoites, which invade epithelial cells of the intestinal wall. Asexual maturation then results in merozoites being released back into the intestinal lumen. These merozoites either result in reinvasion of epithelial cells or undergo maturation to become oocysts. The oocysts may then be excreted or may excyst while still in the lumen to "autoinfect" the host.

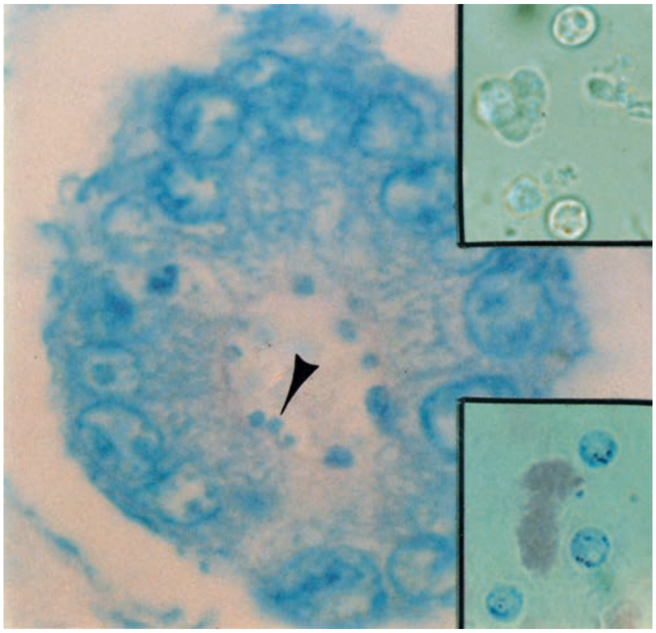

Figure 135-6 *Cryptosporidium parvum* infecting an intestinal crypt *(arrowhead)*. Parasites line the apical surface of the epithelial cells and are covered by host membranes. *Insets*: Oocysts isolated from feces. Upper, organisms isolated after a Sheather's sugar flotation, ×1360. Lower, Giemsa–Jenner stain, ×1360. *(Reproduced with permission from J.A. Fishman, Massachusetts General Hospital.)*

■ Clinical Features

Cryptosporidial infection may be asymptomatic, or it may be associated with a range of illness from mild diarrhea to severe gastroenteritis. Invasion of the intestinal epithelium results in secretory diarrhea. The biliary tree may be infected, causing cholangitis, and hepatitis and pancreatitis also have been described. Infection may be associated with systemic symptoms such as malaise, nausea, and abdominal cramps. In some patients, diarrhea is voluminous and has been described as "cholera-like." In patients with a normal immune system, cryptosporidial diarrhea usually resolves within 2 weeks. In immunocompromised individuals, especially those with HIV infection and CD4 cell counts less than 100 cells/mm^3, symptoms often continue until the immune status of the individual is restored. In such individuals, cryptosporidiosis may result in a severe wasting syndrome.

■ Pulmonary Cryptosporidiosis

Respiratory infection with *Cryptosporidium* spp. is rare but has been reported, usually in patients with AIDS (Fig. 135-7).[11] Pulmonary involvement, as with other extraintestinal manifestations of cryptosporidiosis, usually occurs in the setting of intestinal disease. At least one case of pulmonary infection, however, has been reported with no apparent evidence of intestinal infection. Pulmonary involvement may appear as an interstitial infiltrative process or as areas of focal consolidation. In a series of 47 organ transplant recipients with cryptosporidiosis, only 1 had pulmonary involvement.[12]

Some authors suggest that the prevalence of pulmonary cryptosporidiosis is underestimated, and one study reported a prevalence of 17% in HIV-positive patients with respiratory symptoms. Pulmonary cryptosporidiosis with *C. baileyi*, an avian parasite, has also been reported in a human with a pulmonary hamartoma.[13]

■ Diagnosis

Cryptosporidium may not be cultured in vitro, and diagnosis of cryptosporidiosis relies largely on demonstration of pathologic

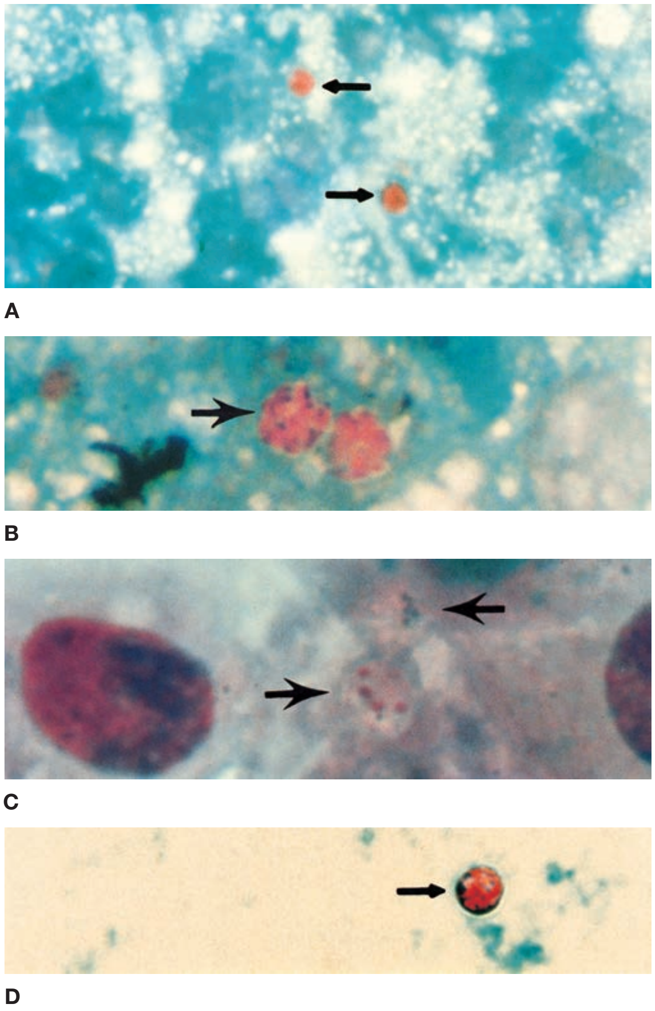

Figure 135-7 Pulmonary cryptosporidiosis. **A.** Touch preparation from a lung biopsy of a patient with AIDS. *Arrows* show organisms stained with a modified acid-fast stain (modified cold Kinyoun, MCK), which stains the organisms red (×880). **B.** Same preparation and stain as (**A**) showing internal red-black dense granules *(arrow)* characteristic of the organism. **C.** Same preparation as (**A**) showing similar morphology *(arrow)* using a rapid Giemsa Hemacolor stain. **D.** Sputum stained with MCK technique reveals organisms *(arrow)*. *(Reproduced with permission from Dr. P. Ma.)*

findings in tracheal or bronchial tissues, and visualization of cryptosporidial cysts by microscopy. The cysts may be best seen by acid-fast staining of specimens. Oocysts have been detected in bronchoalveolar lavage, open lung biopsy, and sputum specimens.

■ Treatment

Nitazoxanide decreases diarrhea in immunocompetent individuals with intestinal cryptosporidiosis. However, reliable efficacy has not been demonstrated in individuals with disseminated cryptosporidial disease, or those who are immunocompromised. Thus, in most individuals, treatment is predominantly supportive while attempts are made to restore immune function; in patients with AIDS, this is chiefly through the use of antiretroviral therapy. In addition to nitazoxanide, other agents have been administered to individuals with cryptosporidiosis, although efficacy has not been demonstrated. Administered agents have included paromomycin, trimethoprim–sulfamethoxazole, rifaximin, and metronidazole. Anecdotally, azithromycin has been successfully combined with paromomycin in the therapy of pulmonary infection.

CYCLOSPORIASIS

Cyclospora cayetanensis is a protozoan organism usually associated with diarrheal illness in humans. It is ubiquitous and transmitted usually as a result of contamination of food or water. The protozoan is usually detected as an approximately 10-μm organism on acid-fast stains of specimens. Infection usually responds to trimethoprim–sulfamethoxazole. There are rare case reports of possible pulmonary cyclosporiasis. A 60-year-old Brazilian man with a history of treated tuberculosis was found to have *C. cayetanensis* organisms in sputum specimens examined for evaluation of respiratory distress and pulmonary infiltrates. No other organisms were detected, and the patient's symptoms resolved following administration of trimethoprim–sulfamethoxazole (and treatment of concomitant intestinal parasitosis). A similar case report from Egypt demonstrated infection with *C. cayetanensis* after treatment for tuberculosis.[14]

SARCOCYSTIS

Sarcocystis spp. are intracellular protozoal coccidian two-host parasites. Humans can be a definitive host for *Sarcocystis hominis* and *Sarcocystis suihominis,* and following ingestion of tissue cysts in undercooked beef *(S. hominis)* or pork *(S. suihominis)*, can develop acute gastroenteritis and excrete oocysts. Alternatively, humans can ingest the oocysts of other predator animals and develop a vasculitis that can manifest as myositis or cardiomyositis, or may involve the lungs, kidneys, and liver. Eosinophilia is prominent. Eventually the parasites encyst in musculature, including cardiac tissue. Diagnosis is usually based on clinical recognition, myositis associated with eosinophilia and a negative trichinella serology, and/or biopsy of muscle. Treatment is usually supportive, often involving steroids. Cases are usually sporadic, although recurrent outbreaks have been associated with Tioman and nearby islands in Malaysia.[15,16]

MALARIA

Malaria in humans is the result of infection by one of five species of plasmodia: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. Human malaria is endemic in parts of sub-Saharan Africa, India, Southeast Asia, the Caribbean, and Central and South America. Hundreds of thousands of deaths annually are attributed to malaria, usually among pregnant women and children under the age of 5 years who live in endemic areas, especially in sub-Saharan Africa. The majority of malaria-related fatalities are a result of infection with *P. falciparum*.

Malaria is acquired by the bite of an infective female *Anopheles* sp. mosquito. In nonendemic areas, malaria cases are found largely in travelers who have returned from malaria-endemic areas, but the parasite also may be transmitted by contaminated blood products, in utero from mother to child, and by organ transplantation. Malaria infection in persons coinfected with HIV is associated with increased HIV viral load and increased symptoms in the setting of parasitemia.

■ Life Cycle

When bitten by an infective mosquito, malarial sporozoites enter the host and travel to the liver, where they invade hepatocytes and divide, forming tissue schizonts in an asymptomatic stage. These schizonts then rupture, releasing thousands of daughter merozoites into the bloodstream. These merozoites invade erythrocytes and develop to form mature ring forms and, ultimately, erythrocytic schizonts. A small percentage of merozoites develop into sexual forms called gametocytes. Gametocytes do not cause symptoms, but when another mosquito bites an infected human host, the gametocytes are ingested by the feeding mosquito, permitting the malarial life cycle to continue. *P. falciparum* may infect red blood cells of all ages, resulting in the potential for very high levels of parasitemia.

Infection with *P. vivax* and *P. ovale* may result in a dormant liver phase in which parasites remain in the liver in the form of hypnozoites, potentially causing relapse many months after first infection. *P. falciparum* and *P. malariae* do not have such a dormant stage, and do not cause late relapsing disease. *P. knowlesi* is a simian malarial parasite that has been diagnosed in humans in areas of Asia.

Pathogenesis

Malaria-related morbidity and mortality occurs predominantly in children and pregnant women. Most individuals who live in endemic areas develop partial immunity to symptomatic disease as they age. This immunity does not prevent infection, but it reduces the frequency of symptoms and severity of disease despite ongoing parasitemia. Infection with any of the five species of malaria causes hemolysis, resulting in anemia that may be severe.

Certain genetic traits associated with hemoglobin structure or erythrocyte surface antigens are associated with decreased infection rates or decreased symptomatic disease. For example, absence of the Duffy antigen on the surface of erythrocytes protects against *P. vivax* infection, and sickle cell trait is protective against severe *P. falciparum* infection. *P. falciparum* also causes the formation of "sticky knobs" on the surface of infected erythrocytes. These knobs comprise host cell and parasite antigens, and they mediate binding of infected erythrocytes to endothelial surfaces. This binding results in sequestration of infected erythrocytes, and may result in "sludging" of blood flow. This sequestration and sludging contributes to microvascular obstruction that can result in organ dysfunction.

Clinical Features

Patients with malaria typically present with fever and a constellation of other nonspecific symptoms such as headache, chills, and myalgias. Vomiting, nausea, diarrhea, and cough also may be present. Anemia, thrombocytopenia, and hepatosplenomegaly may be present. Sequestration of infected erythrocytes in the brain may cause cerebral malaria. Individuals with cerebral malaria may present with altered mental status, seizures, focal neurologic findings, or coma. Even with treatment in modern intensive care units, mortality during cerebral malaria is high. Other organ-specific complications of infection are also largely related to microvascular sequestration of parasitized red blood cells in specific tissues, and may manifest as placental, renal, or pulmonary dysfunction (Fig. 135-8).

Pulmonary Features

Pulmonary symptoms such as cough and increased respiratory rate are common during malaria.[17] In African children, malaria frequently presents with symptoms and signs suggestive of pneumonia. Metabolic acidosis is an important cause of respiratory distress in these children, but pneumonitis as a result of sequestered parasitized red blood cells is also responsible. In more severe disease, noncardiogenic pulmonary edema may develop. Initial acute lung injury may progress to ARDS (Fig. 135-9).[18] Tachypnea and dyspnea, followed by hypoxemia and respiratory failure, may develop. Studies have confirmed the development of impaired alveolar–capillary membrane function in patients with severe malaria. Lung injury in severe disease is postulated to be not only the result of pulmonary microvascular sequestration, but also a consequence of the inflammatory response to infection.

In a study of uncomplicated symptomatic malaria, altered pulmonary physiology, including increased airflow obstruction, decreased gas transfer, impaired ventilation, and increased pulmonary phagocytic activity were found in both *P. vivax*– and *P. falciparum*–associated infections, but were worse in cases of *P. falciparum* malaria.[19] ARDS has also been reported in cases of malaria caused by *P. vivax*, and one case of pulmonary edema has been reported complicating

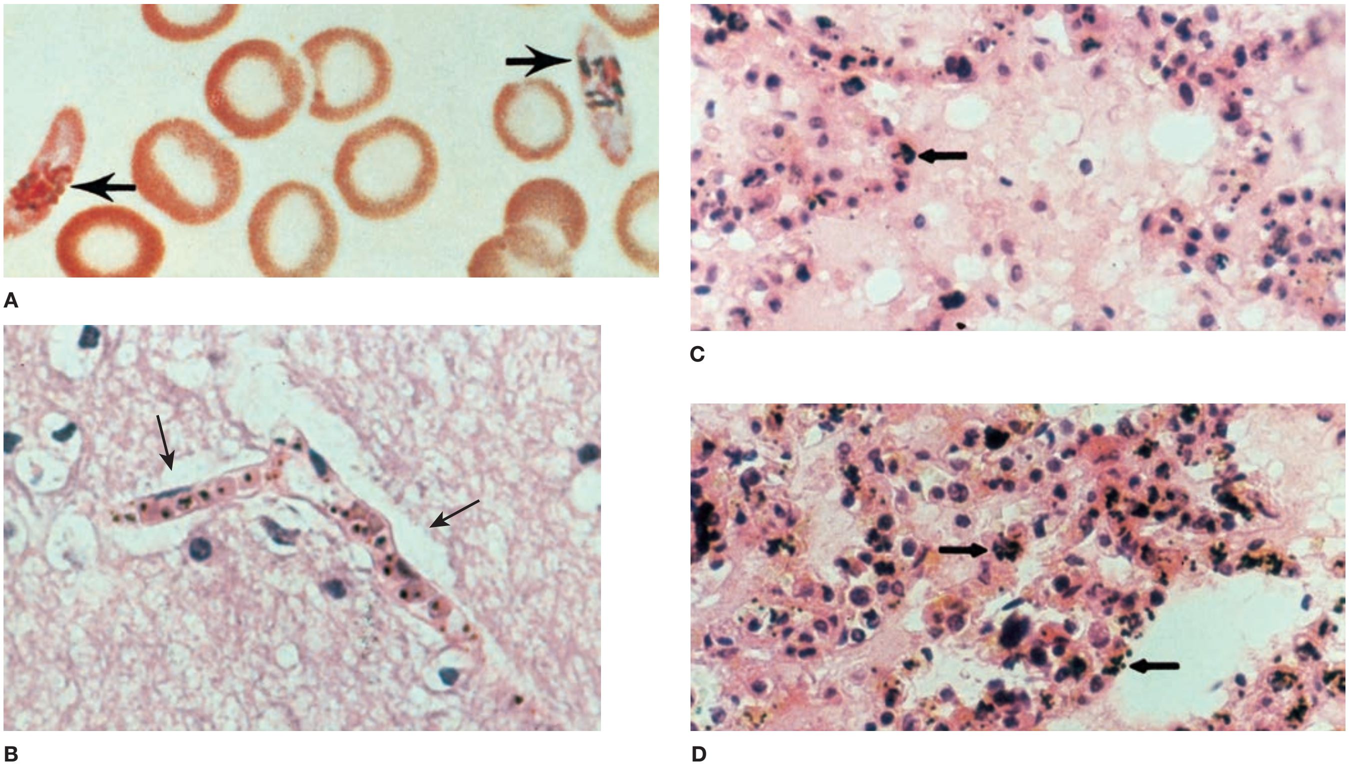

Figure 135-8 *Plasmodium falciparum*. **A.** Banana-shaped gametocytes on peripheral blood smear *(arrows)*. This form is only seen with falciparum malaria (Wright stain, ×1375). **B.** Cerebral vessels obstructed by parasitized red blood cells *(arrow)* with surrounding edema (hematoxylin and eosin stain, ×1375). **C.** Acute pulmonary edema due to pulmonary venular occlusion (organism at *arrow*; hematoxylin and eosin). **D.** Deposition of malarial pigment *(arrows)* in vicinity of occluded pulmonary vessels.

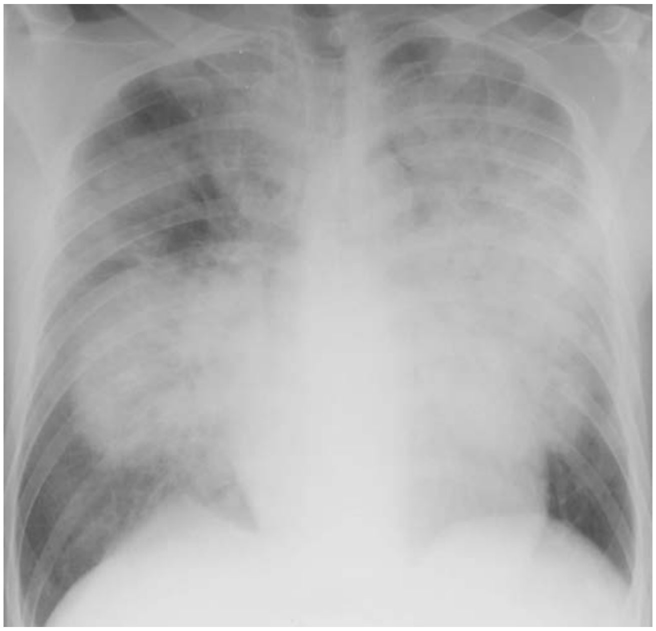

Figure 135-9 ARDS in a 31-year-old man with *P. falciparum* malaria. Chest radiograph demonstrates patchy bilateral areas of increased opacity. *P. falciparum* trophozoites were found in a thick blood smear. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

a case of *P. ovale* malaria.[20] Pulmonary involvement also occurs during *P. malariae* infection;[21] however, significant pulmonary morbidity is largely confined to infection by *P. falciparum* and usually occurs in the context of multisystem involvement. The principal differential diagnosis for pulmonary disease in malaria infection is metabolic acidosis and bacterial pneumonia.

■ Diagnosis

The diagnosis of malaria should be considered in any symptomatic patient who has had exposure to the parasite in a malaria-endemic area. Rare cases of transmission by blood products, organ transplantation, or congenital infection also have occurred. Individuals with malaria caused by *P. falciparum* usually develop symptoms within 3 months of the mosquito bite, and usually within 1 month. Since *P. vivax* and *P. ovale* have potentially dormant liver phases, individuals infected with these parasites may not develop symptoms for many months after exposure (usually within 1 year of the mosquito bite).

Malaria is usually diagnosed through microscopic examination of blood smears, or with antigen-based rapid diagnostic tests (RDTs).

■ Treatment

Appropriate treatment of individuals with malaria depends on the infecting species, severity of disease, age and pregnancy status, and the ability of the patient to take drugs by mouth. Non-falciparum malaria is generally susceptible to chloroquine phosphate, although to date, resistance has been reported in parts of Indonesia, Papua New Guinea, India, Myanmar, and Brazil. The World Health Organization now recommends that individuals with chloroquine-resistant *P. falciparum* malaria be treated with artemisinin-based combination therapies (ACTs) that include an artemisinin derivative with a second agent such as lumefantrine, amodiaquine, pyronaridine, piperaquine, or mefloquine. Less optimal alternatives include oral atovaquone–proguanil or mefloquine, or quinine sulfate in combination with either doxycycline or clindamycin. Individuals with severe disease can receive intravenous artesunate in the United States, followed by an oral combination therapy. Less optimal alternatives include parenteral quinine dihydrochloride or quinidine gluconate with a second agent.

Individuals with malaria caused by *P. vivax* or *P. ovale* also should be treated with primaquine to treat the hypnozoite form of disease. Primaquine should not be administered to individuals deficient in glucose-6-phosphate dehydrogenase or to pregnant women. Pulmonary manifestations and other organ-specific complications of severe infection are treated supportively. Mechanical ventilation may be required. Early institution of renal replacement therapy may prevent subsequent development of ARDS in severe malaria. Exchange transfusion has been used for patients with severe falciparum-associated disease with parasitemia levels over 5%, although data on efficacy are controversial.

BABESIOSIS

Babesiosis is a tick-borne infection usually caused by *Babesia microti* in the United States, and *Babesia divergens* in Europe. In the United States, the majority of cases occurs in New England, Mid-Atlantic and Upper Mid-West. Transmission also may occur as the result of infected blood transfusions.

Babesia parasites invade, multiply within, and lyse red blood cells. In immunocompetent hosts, disease is most commonly asymptomatic or relatively mild, and characterized by fever, flu-like illness, myalgias, and nausea. More severe manifestations may include thrombocytopenia, hemolytic anemia, jaundice, meningismus, noncardiogenic pulmonary edema, disseminated intravascular coagulation, hypotension, and shock. Severe disease is most common among the elderly or individuals with compromised immunity. Asplenic individuals are at particular risk of severe disease, and individuals infected with HIV or following organ transplantation are at particular risk of persistent disease. Pulmonary disease in babesiosis occurs in association with multisystem disease, and usually presents as ARDS or noncardiogenic pulmonary edema or ground-glass opacification.[22,23]

The diagnosis of babesiosis should be considered in any patient with appropriate exposure history who presents with fever or a sepsis syndrome. Diagnosis is usually confirmed by microscopic examination of peripheral blood. Atovaquone, azithromycin, quinine, and clindamycin all have anti-*Babesia* activity; combination therapy is usually administered; exchange transfusion can also be considered.

TRYPANOSOMIASIS

American and African trypanosomiasis are considered below.

■ American Trypanosomiasis (Chagas Disease)

Chagas disease is caused by infection with *Trypanosoma cruzi*, a protozoan parasite transmitted to humans most often via the feces of an infected reduviid bug. The disease is endemic in certain South and Central American countries. Infection has also occurred following solid organ transplantation including lung.[24]

Clinical manifestations may occur acutely after initial infection. More commonly, clinical manifestations may not become evident until years or decades after initial infection. When acute symptoms do occur, they may include fever, peripheral edema, hepatosplenomegaly, and myocarditis. Chronic sequelae may occur in up to one-third of infected individuals and usually involve the heart, esophagus, or large bowel (Fig. 135-10).

Cardiac disease usually manifests clinically as congestive-dilatory cardiomyopathy.[25] Chronic dilatation of the esophagus or colon resulting from denervation of the gut may result in Chagasic megaesophagus or megacolon. Acute myocarditis may result in pulmonary edema. Pulmonary involvement during Chagas disease is usually secondary to cardiac or intestinal disease, and may include pulmonary edema secondary to congestive heart failure, pulmonary hypertension secondary to right-sided dilatory cardiomyopathy, or aspiration pneumonia secondary to vomiting and regurgitation associated with megaesophagus or megacolon. Recurrent aspiration and pneumonitis may lead to lung abscesses, fibrosis, scarring, and bronchiectasis. The debilitation of chronic Chagas disease may lead to cachexia, and may be associated with a higher rate of tuberculosis. In an autopsy review of 69 adult cases of Chagasic megaesophagus in Brazil, 35% of patients had pneumonia, and 22% had pulmonary tuberculosis—rates that were higher than in a cohort of patients in the same study who had Chagasic cardiac disease but no megaesophagus.
